-bound I^{131} in plasma in duplicate tracer experiments in ...p of patients not given any antithyroid drug: stippled 1st experiment; hatched columns, 2nd experiment.

king together of urine collected during the nty-four hours following the tests is partly le for the large values of the standard deviation, e values are undoubtedly influenced by urine normal amounts of radioactivity before the had time to act. There is clearly a large in the daily output of radio-iodine following ation of both drugs. There is, however, no significant difference in daily output between ated and methylthiouracil-treated patients.

RADIO-IODINE IN PLASMA

lioactivity of the blood-plasma, both total and ound, was measured in terms of the percentage gested dose per litre of plasma. The liquid were counted generally to give at least 500 i.e., with a coefficient of variation of less than It is known that the techniques adopted for counting give results reproducible within error of counting, when the total activity in ma at a given time is measured. For measure- Protein-bound radioactivities, involving separate procedures on different specimens of blood, the reproducible generally to within 10%.

lts of the measurements of the protein-bound ity in the plasma in the three groups of patients out in figs. 4–6. In these diagrams, and in –VI, the plasma radioactivity levels have been o the thyroid radio-iodine levels. This has been cause methylthiouracil produced large changes hyroid radio-iodine levels, and the results of the a would not otherwise have been comparable. ma values quoted are therefore the amounts of ive iodine per litre of plasma, expressed as a ge of the total radioactivity in the gland at the h blood sample was taken.

Patients

illustrates the reproducibility of results obtained acer experiments are repeated at an interval of two weeks in untreated patients. The ratio of plasma activities at comparable times during the two tests was calculated, and table III gives the mean values of this rate for both total and protein-bound radioactivity.

6723

TABLE III—UNTREATED GROUP OF PATIENTS

Mean ratio of total plasma radioactivity (11 samples)	0·90 ± 0·13
Mean ratio of protein-bound radioactivity (11 samples)	0·93 ± 0·18

The standard deviation expressed here includes not only the real variation between plasma samples taken at comparable times in successive tracer experiments but also the counting errors and, in the case of chemical procedures, the pipetting and chemical errors.

Iodide-treated Patients

In patients treated with iodide (fig. 5) there is a considerable fall of the plasma levels in the second tracer experiment compared with the control values in the first experiment, the values of the ratio being set down in table IV.

TABLE IV—PATIENTS TREATED WITH IODIDE

Mean ratio of total plasma radioactivity (15 samples) ..	0·48 ± 0·28
Mean ratio of protein-bound radioactivity (15 samples)	0·52 ± 0·31

Though the protein-bound radioactivity comprises the major portion of the total activity, the standard deviatio for these measurements is higher than for the total plasm radioactivity measurements. This is partly because greater error in measurement and partly because th proportion of protein-bound iodine varied somewhat from patient to patient. Insufficient evidence is available

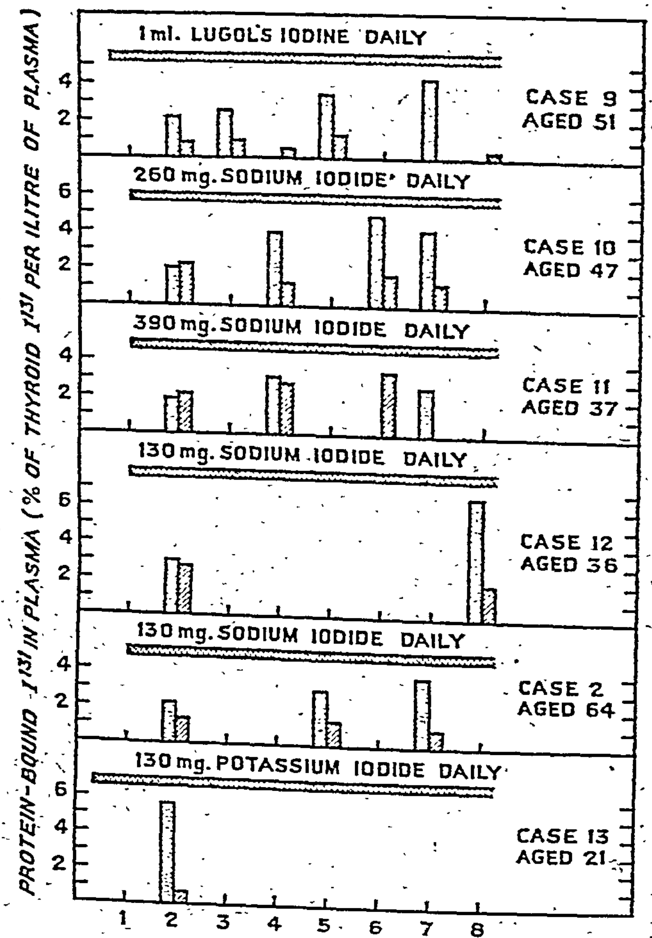

Fig. 5—Protein-bound I^{131} in plasma in duplicate tracer experiments in 4 patients given sodium iodide, 1 patient given Lugol's iodine, and 1 patient given potassium iodide during 2nd experiment: stippled columns, 1st experiment; hatched columns, 2nd experiment.

in our experiments to give a firm explanation of these variations.

The ratios cited above for the effects of iodide on plasma radioactivity include all the observations on plasmas [illegible] later than twenty-four hours after giving the I131 [illegible] o shows clearly that the values taken only one day after the start of the iodide (I^{127}) administration are less influenced than later plasma values. This is one reason for the large values of the standard deviation cited for these figures.

The ratios worked out using only plasma taken two days after the drug or later—i.e., three days or later after giving the tracer I^{131} dose—are shown in table V.

TABLE V—PLASMA RADIOACTIVITY TWO DAYS OR MORE AFTER TREATMENT WITH IODIDE

Mean ratio of total plasma radioactivity (9 samples)	0·36 ± 0·10
Mean ratio of protein-bound radioactivity (9 samples)	0·39 ± 0·19

It will be noted that in one case (case 11) in fig. 5 a reduction in plasma radioactivity following administration of iodide was not observed. These values were, however, included in the mean ratios cited above. In the 5 other patients there was a significant reduction in plasma radioactivity after the administration of iodide.

Methylthiouracil-treated Patients

The plasma radioactivity in the methylthiouracil-treated patients (fig. 6) showed less change compared with the control values; in fact the radioactivity observed was about proportional to the total radioactivity of the gland at the time the blood was taken. The ratios for this group are given in table VI.

TABLE VI—PATIENTS TREATED WITH METHYLTHIOURACIL

Mean ratio of total plasma radioactivity (13 samples)	1·04 ± 0·18
Mean ratio of protein-bound radioactivity (12 samples)	0·97 ± 0·18

The ratios obtained when the calculations are restricted to samples of blood taken after forty-eight hours from the start of the administration of the drug are shown in table VII.

TABLE VII—PLASMA RADIOACTIVITY TWO DAYS OR MORE AFTER ADMINISTRATION OF METHYLTHIOURACIL

Mean ratio of total plasma radioactivity (7 samples)	0·96 ± 0·20
Mean ratio of protein-bound radioactivity (6 samples)	0·88 ± 0·20

There is a suggestion, therefore, that the relative blood level may also be depressed by methylthiouracil after some time; but this is uncertain, and it is clearly much less than when iodide is used.

SUMMARY OF RESULTS

Iodide administered in the quantities described, after the peak of the uptake curve has been passed, has little influence on the rate of fall of the thyroid radio-iodine level, but does depress the level of radioactive thyroid hormone in the plasma. By contrast, the administration of methylthiouracil after the peak causes an increased rate of fall of thyroid radioactivity, but the plasma dioactivity remains unchanged relative to the thyroid-level. Finally, the urinary excretion of radio-iodine is ased by both iodide and methylthiouracil.

Discussion

ioactive iodine administered orally as sodium is rapidly absorbed into the blood-stream, from it is then removed mainly by the thyroid gland the kidneys. In untreated thyrotoxic patients 80% of the radio-iodine is taken up by the thyroid a few hours, and the greater part of the remaining excreted in the urine. The radio-iodine taken up thyroid rapidly enters into organic combination, radioactive monoiodotyrosine, diiodotyrosine, roxine (Taurog et al. 1950). By the time the take has been reached, the gland has already to liberate radioactive hormone into the blood. The level of radioactive hormone in the plasma nues to rise for several days, after which it usually reaches a plateau (Pochin 1950). This hor in the tissues, where it is eventually liberating radio-iodide. This liberated iodi the cycle again, being divided between t the kidneys in the same ratio as before.

The thyroid radio-iodine curve can be div into an uptake phase and a release ph here with the effect of drugs administer release phase. The shape of the curve i due in the main to the resultant of two o release of radioactive hormone, which ten the gland radioactivity; and (2) the reac the thyroid of radio-iodide from broken hormone, which tends to increase the gland. When methylthiouracil is administered du phase it prevents the synthesis of thyroid suppresses the reaccumulation in the gl iodide liberated by this breakdown of h tissues. The gland radioactivity therefo rapidly than it would otherwise do, a iodide not converted into protein-bound fo in the urine. The fact that there is no subst in the plasma-hormone radioactivity administration of methylthiouracil sugg increase in the rate of fall of the gland r not associated with an increased rate of rele hormone from the gland. While this

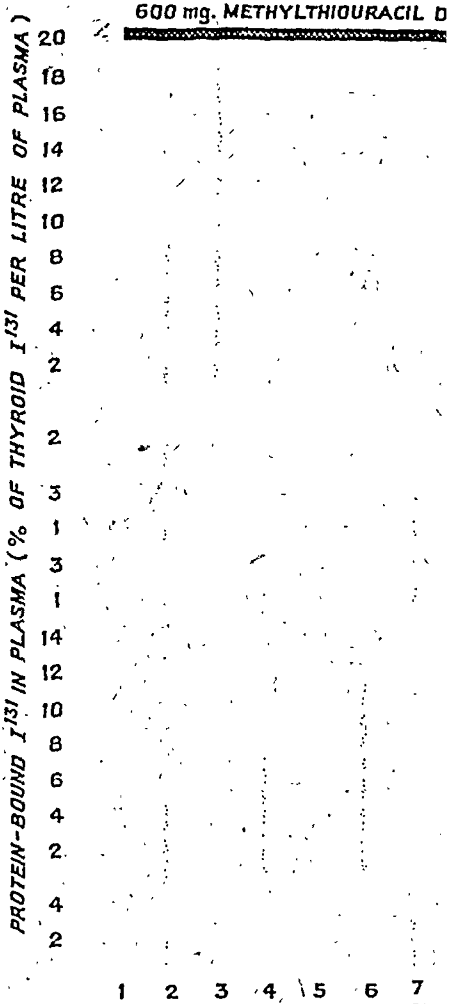

Fig. 6—Protein-bound I^{131} in plasma in duplicate trace 6 patients given methylthiouracil during 2nd exper columns, 1st experiment; hatched columns, 2nd

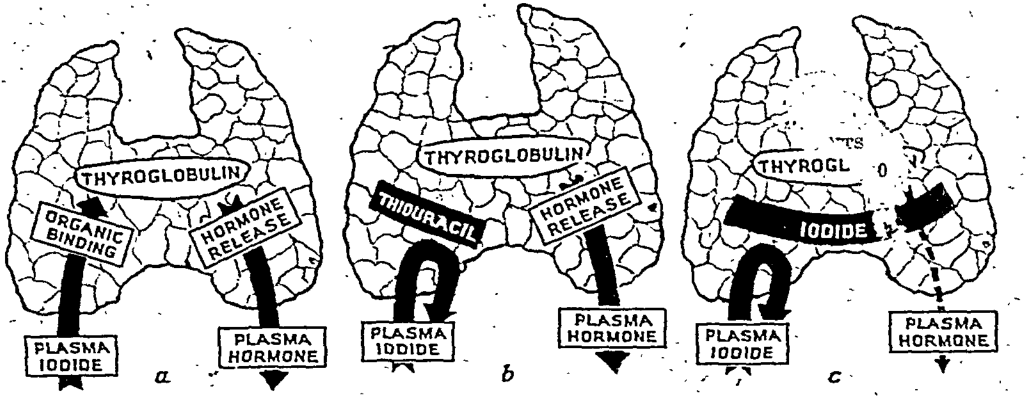

Fig. 7—Site of action of thiouracil and sodium iodide in thyrotoxicosis:

(a) In the untreated patient radioactive iodine is removed from the plasma by the thyroid and rapidly bound into an organic state, being stored in the gland as thyroglobulin. Subsequently the thyroglobulin is broken down, liberating thyroid hormone, which is secreted into the blood-stream.

(b) The thiouracil group o compounds block the organic binding of iodine with the result that radio-iodide picked up by the thyroid cannot be stored and is therefore rapidly returned to the plasma unchanged. The release mechanism is, however, not affected; hence hormone synthesised before the start of thiouracil therapy is secreted into the blood-stream until the supply of hormone in the gland has been exhausted.

(c) A possible way in which iodides may act in thyrotoxicosis by blocking both the organic binding of iodide and the release of preformed thyroid hormone. The arrow showing the release of thyroid hormone has been drawn as an interrupted line to indicate that the block is probably incomplete.

here is an increase in the urinary excretion of
dicating that the reaccumulation of radio-iodide
roken-down hormone has been suppressed. With
thiouracil this increased urinary excretion is
ted with an increased rate of fall in thyroid
tivity, whereas with sodium iodide there is no
decrease of thyroid radioactivity. In addition
sma radioactive hormone levels are lowered after
ministration of iodides. Our findings would be
ent with a mechanism whereby the sodium iodide,
suppressing the reaccumulation of radio-iodide,
ows the release from the thyroid of preformed
tive thyroid hormone, thereby preventing any
e in the rate of fall of gland radioactivity.
onsequence of the diminished delivery of radio-
thyroid hormone to the blood, the radioactive
ne in the blood is not replaced at a rate sufficient
mpensate for its breakdown, and the plasma
tivity levels therefore fall.

nterpretation of these effects is not easy without
dditional information that would be given by
measurements of both the radioactive and
oactive iodine compounds in the plasma

tempting to assume that the high iodide level in
sma reduces both the rate at which the iodide is
sised into thyroid hormone and the rate at which
mpound is delivered from the thyroid to the
. If this were true, the observations would offer
planation of the well-known clinical fact that the
tic effect of iodide is more rapid than that of
acil. In the case of iodide the supply of hormone
body would be decreased immediately, whereas
case of thiouracil the stock of hormone in the
has first to be exhausted before the supply to the
s affected. The suggested mode of action of these
is shown diagrammatically in fig. 7.

fact that no significant change was observed in
te of fall of the level of radioactive iodine in the
when large doses of iodide were given, seems to
t that there is at least an approximate compensa-
etween the suppression of the reaccumulation of
iodide from hormone breakdown and the inhibition
release of the radioactive thyroid hormone from
and.

e must be taken, however, in assuming that the
iour of I^{131} accurately indicates the behaviour of the normal iodine atom when the iodine cycle is disturbed by the administration of large amounts of inactive iodide. For example, if appreciable quantities of the newly administered I^{127} were synthesised into thyroid hormone in the gland, the specific activity of the gland hormone would decrease. If the gland, therefore, could secrete a fixed quantity of the hormone per unit time into the plasma, the amount of radioactive hormone put out by the gland would decrease. This possibility cannot be eliminated with certainty until more complete chemical analyses of the active and inactive components of the iodine cycle are available. Nevertheless it should be remembered that the clinical remission shown by patients receiving I^{127} suggests that the output of thyroid hormone is in fact decreasing.

The possibility was also considered that the high plasma-iodide level might in some way have increased the rate of breakdown of the thyroid hormone peripherally and thereby have increased the rate of excretion. To test this possibility measurements were made of the rate of disappearance from the plasma of biologically synthesised radioactive thyroid hormone injected into two groups of thyroidectomised rabbits. One group was given large doses of iodide, and the other was fed on a low-iodine diet. These measurements showed no significant difference in the rate of decrease of plasma radioactivity in the two groups. We conclude therefore that a peripheral effect of iodides of this nature probably does not contribute significantly to the results described with thyrotoxic patients.

In conclusion, therefore, it can be stated that the experimental results indicate that large doses of I^{127} do reduce the rate at which the radioactive hormone is lost from the gland to the plasma. This may point to a real reduction in hormone output from the gland when the plasma-iodide level is high. The possibility, however, that changes of specific activity of the hormone play an important rôle has not been entirely eliminated.

Summary

Tracer experiments using radioactive iodine (I^{131}) were made in duplicate on three groups of thyrotoxic patients. One group was given no drugs and was used as a check on the reproducibility of the results. A second group was given methylthiouracil, and the third group sodium iodide, during the second tracer experiment. The drugs were administered in each case after the peak uptake of the radio-iodine in the gland had been passed.

The rate of fall of the gland radioactivity was much increased by the administration of methylthiouracil but was unaffected by sodium iodide. At the same time the radioactivity in the plasma was substantially lower after iodide had been given than after methylthiouracil. The urine output of radioactive iodine was increased by both drugs.

It is suggested that high plasma-iodide levels, besides blocking the organic binding of I^{131} in the gland, an action similar to that of methylthiouracil, also slow down the release from the gland of preformed radioactive thyroid hormone. This probably indicates a real reduction in hormone output from the gland, though a complete interpretation of the results is not possible without a knowledge of the specific activities of the iodine compounds present in the cycle.

We are greatly indebted to Prof. E. J. Wayne for permission to undertake these studies on patients under his care, and for his interest and criticism. We also wish to thank Dr. Joyce Burke, Dr. A. G. Macgregor, and Dr. D. R. Wood, for their help, and Miss L. Fearn, Miss L. Mann, Mr. E. Salvin, Mr. D. Gow, and Mr. L. Leeming for technical assistance.

EFFECT OF INDUCED VASCULAR HYPOTENSION ON THE LIVER

ALTERATIONS IN APPEARANCE AND CONSISTENCE

P. R. Bromage

M.B. Lond., D.A.

CONSULTANT ANÆSTHETIST, CHICHESTER AND PORTSMOUTH HOSPITAL GROUPS

The technique of controlled vascular hypotension in surgery is fashionable, and has the sanction of the following argument. The level of the systemic arterial blood-pressure is immaterial, provided that adequate capillary circulation exists; this is ensured when the pressure at the arteriolar end of the capillary exceeds the sum of the venous pressure and the colloid osmotic pressure of the plasma, a total of about 32 mm. of Hg in normal man (Landis 1930). Arterial pressures in excess of 32 mm. are expended solely in overcoming the peripheral arteriolar resistance, which stands guard, as it were, between the heart's excess and the capillary bed. It follows that if the arteriolar resistance is removed, a systolic pressure a little in excess of 32 mm. will suffice for tissue requirements (Griffiths and Gillies 1948).

It is agreed by all that such a procedure reduces the margin of safety. There is no reserve of pressure to increase the rate of capillary flow in response to anoxæmia, and a brief anoxic episode, well borne by a normotensive patient, will not be tolerated in the presence of profound hypotension. But it is granted, grudgingly perhaps, that although the bounds of physiological rectitude are approached by this technique, they are not exceeded where primary capillaries receiving arterial blood are considered.

THE BLOOD-SUPPLY OF THE LIVER

The liver is in different case, and a consideration o anatomy and physiology of its blood-supply will
show that a higher critical level of hypotensi
expected for the liver than for other tissues;
this level and 32 mm., the local circulati
deficient in the liver, in spite of adequate
circulation elsewhere.

Hepatic sinusoids receive blood from two s
hepatic artery and the portal vein, both of
capable of wide functional variation to suit

fistula (McIndoe 1928), or after excision of the
(Child et al. 1952) or ligation of the hepatic
portal hypertension in Laennec's cirrhosis
et al. 1949, Reinhoff 1951, Gray 1951). No
hepatic artery supplies up to 20% of the to
inflow at a constant high oxygen-tension (95%
(Blalock and Mason 1936), but the quantit
by this route is variable, and decreases du
lation of the sympathetic nerves in the hep
(Burton-Opitz 1912).

The liver sinusoids are a primary set of cap
the hepatic-artery blood, but a secondary s
laries for the portal blood. The oxygen c
made by the portal blood depends upon the
through the primary capillary net in the mu
brane of the intestinal tract and upon the oxy
there. Barclay and Bentley (1949) and Ba
(1951) have shown that during sympathetic s
arteriovenous channels open in the submucos
the stomach, the capillary net is by-passed, and
venous blood becomes arterial in character
oxygen saturation of 91% instead of 74%. Th
sympathetic stimulation, responsibility for t
supply to the liver is shifted from the meag
artery to the stout portal vein, by way of art
channels in the submucosa. It might be sup
the reverse would occur in the presence of sy
paralysis. Arteriovenous channels in the
remain closed, and blood would take the lo
through the mucosal capillaries, arriving at the
relatively deoxygenated state. The hepatic arte
be dilated, and contributing its maximum (i.e
to the hepatic inflow.

Under conditions of sympathetic paralysis
blood-pressure it is possible to imagine a point
the blood-flow is so slow that a high degree of
desaturation occurs in the intestinal capillaries,
oxygen tension of the blood in the portal vein
as low as that of the blood in the hepatic vein (M
1937). The liver will then depend upon the
artery for its entire oxygen supply. If the flow
the hepatic artery should be inadequate for t
needs of the liver, local tissue anoxia will occu

Shorr et al. (1945, 1948) have shown th
depressor material (V.D.M.), a substance that h
identified with ferritin, a protein linked wi
(Granick 1951), is formed in the liver under
conditions, and that it is inactivated by its
origin under aerobic conditions. It might be
that the anoxic level at which reversal of the
hepatic V.D.M. mechanism took place would be
by a simultaneous local vasodilatation in the liv
If sufficiently intense, this vasodilatation might
the colour and size of the liver to such an extent
detected by the naked eye. Such changes ha
observed in animals; hepatic engorgement an
soidal dilatation were found in rabbits, guineap
rats exposed to low oxygen-tensions for long
(Campbell 1927, 1928).

STUDY OF HEPATIC CHANGES

Observations were therefore made on the mac
appearance of the livers of 17 patients durin

operations under conditions of controlled otension to find out whether any gross to be seen at low blood-pressures. Patients or liver disease were excluded from the erential epidural block—i.e., sympathetic , but not motor, block—was induced by method under thiopentone and nitrous oxide/ sthesia, and the upper level of analgesia was the second thoracic segment or higher. The were delivered through a large-bore endo- in the proportions of 1 part oxygen to 2 s oxide at a high-rate of flow throughout the The blood-pressure was allowed to fall to its l during the early stages of the operation in (Bromage 1951), but if the systolic pressure 40 mm. it was corrected with a small dose of etamine (' Methedrine ') or *l*-noradrenaline. was inspected for colour and teneness of the l the surgeon was asked to palpate the organ ote its degree of flaccidity or turgidity. A uantity of vasopressor drug was then given ously—either 5–7 mg. of methedrine, or 50–200 oradrenaline as a continuous infusion at the rate g. per minute. After the systolic pressure had 70 mm. or higher, the liver was again inspected pated. The cases in this series were distributed five surgeons, whose lack of bias was encouraged ping them in ignorance of the purpose of the ation for as long as possible.

RESULTS

patients there was no detectable change in the ance or consistence of the liver after raising the ressure from low to normal levels.

he remaining 14 patients there were definite s. With a systolic pressure of 60 mm. or less, the ppeared darker than normal; the rich-brown darkened and developed a slaty shade of grey. raising the blood-pressure for some minutes, the r brown of the normal liver returned; the ce in colour was rather like that between plain lk chocolate. Sometimes a marbled-pink network be made out on the surface of the liver as each lobule became edged round with pink.

χ^2 test may be applied to the results for the two mous variables of blood-pressure and liver colour. pplying Yates's correction for continuity (Fisher and 943), $\chi^2_c = 20{\cdot}5$, n = 1. The chance of arriving at this or χ^2 on a basis of "no correlation" would be less ne chance in a thousand similar trials. Therefore the tion of colour change in the liver and falls of systolic ressure to 50–60 mm. is highly significant.

tence

consistence of the liver was changed in 11 patients; other 6 no change was felt. With systolic pressures en 45 and 60 mm., the surgeons described the livers ling either normal to the touch or definitely and rubbery. When the consistence changed at pressures, a liver that had been described as normal feel flabbier, and one that had been turgid would to a normal consistence. In some cases fine les appeared in the peritoneum on the anterior e of the liver, like those in the peritoneal coat of terus after cæsarean section—a sure indication he underlying organ has decreased in bulk. In 3 6 patients in whom noradrenaline was used as the r agent, the blood-pressure was allowed to fall a d time and in each case swelling and darkening of ver recurred. In these patients, by careful adjust- of the noradrenaline drip, it was possible to main- he systolic pressure at a steady level between 60 0 mm. for some time. So long as the pressure ned even slightly above 60 mm. the liver retained its normal appearance, but a fall to 50 mm. was sufficient to change the colour and consistence.

CHANGES IN APPEARANCE AND CONSISTENCE OF THE LIVER IN RESPONSE TO ALTERATIONS OF BLOOD-PRESSURE

Case	Age (yr.)	Resting blood-pressure (mm.Hg)	Low blood-pressure		Pressor drug	Raised blood-pressure	
			Blood-pressure (mm.Hg)	Liver appearance		Blood-pressure (mm.Hg)	Appearance of liver
1	37	125/80	50/30	D, S	m	100/70	L, S
2	27	120/80	55/35	D, T	m	110/80	L, S
3	56	190/100	60/40	D, T	m	120/80	L, S
4	69	120/70	58/28	D, S	m	102/55	L, S
5	62	125/70	60/40	L, S	m	110/75	L, S
6	48	130/70	45/30	D, T	m	78/58	L, S
7	69	170/105	60/40	D, S	m	70/45	L, S
8	67	140/85	35/?	D, S	m	75/45	D, S
9	57	165/90	55/35	L, S	none	80/60	L, S
10	66	145/90	45/30	D, T	n-a	100/80	L, S
11	61	150/90	55/40	D, T	n-a	80/60	L, S
12	34	120/75	58/40	D, T	n-a	120/90	L, S
13	63	120/80	50/?	D, T	m	70/?	L, S
14	63	160/85	58/40	D, T	n-a	120/85	L, S
15	65	170/85	55/35	D, T	n-a	120/80	L, S
16	39	140/80	55/?	D, T	m	105/70	L, S
17	51	120/80	45/30	D, T	n-a	75/55	L, S

D = dark; T = turgid; L = light; S = soft;
m = *d*-methylamphetamine (' Methedrine ');
n-a = *l*-noradrenaline.

Applying the χ^2 test to the degree of correlation between low blood-pressure and change of consistence, $\chi^2 = 13{\cdot}43$. With one degree of freedom, $p = .<0{\cdot}001$. Therefore the association is highly significant.

The results are summarised in the table. The normal liver is described as "light" and "soft," and the abnormal organ, manifestly the seat of local anoxic vasodilatation, as "dark" and "turgid."

DISCUSSION

It is unlikely that the turgor and darkening of the liver, seen when the systolic pressure was below 60 mm. was caused by anything other than local V.D.M. release in response to local tissue hypoxia. Contraction of a sphincter in the hepatic veins has been invoked as an explanation of increased intrahepatic pressures, but no such muscular sphincter has been demonstrated in man, despite assumptions that a hepatic "sluice mechanism" exists (Katz and Rodbard 1939). Moreover, the action of this hypothetical sphincter was supposed to account for changes caused by sympathetic stimulation—not sympathetic paralysis. Although no measurements of cardiac output were made in this series, a watch was kept for adequate capillary filling in other tissues. No great changes were found in the arteriolar-capillary refill-times in the skin, and it would be difficult to explain the obvious local hepatic changes by a fall in cardiac output and generalised vasodilatation.

A vasopressor drug such as methedrine or noradrenaline may counteract hepatic anoxia under these conditions by its generalised vasopressor effect and by raising the perfusion pressure through the liver, or by reopening arteriovenous channels in the intestinal wall thus increasing the oxygen tension in the portal vein. The first possibility is the more probable; for Bearn et al. (1951) have shown that, while splanchnic vascular resistance is decreased by adrenaline, it is slightly increased by noradrenaline. As noradrenaline was used in 5 patients whose livers changed quite definitely from dark and turgid to light and soft, it seems that here at least arteriovenous anastomoses played no part in improving the oxygenation of the liver, and that recovery was produced entirely by the increased perfusion pressure.

The critical level at which liver changes took place was surprisingly constant in this series, for the resting blood-pressures varied between 120/75 and 190/100. It is possible that with a larger series, and with quantitative methods of measuring transhepatic blood flow, a higher critical blood-pressure might be found in hypertensive patients. The critical threshold would be further raised by anything tending to increase local hepatic anoxia, such as anoxæmic anoxia from any cause, or existing hepatic disease (Kaufman et al. 1950). Conversely the threshold would be lowered by factors increasing hepatic oxygenation (Frank et al. 1946, Delorme 1951). It follows that controlled vascular hypotension should be used with extreme caution, if at all, in any patient with diminished hepatic function; when it is used, a clear airway and adequate oxygenation should be guaranteed throughout.

It may be argued that, despite this demonstration of local hepatic anoxia at systolic pressures below 60 mm., many patients have been kept at lower levels for a long time during controlled vascular hypotension, and have suffered no apparent harm: *experientia docet.* That is so, but it is possible that these patients have suffered occult liver damage from the temporary hepatic hypoxia (Delorme 1951), and that they will fall victims to hepatic disease more readily in the course of time. Watch should be kept for the delayed onset of hepatic disease in patients who have been submitted to prolonged vascular hypotension. In the meantime, 60 mm. should be regarded as the lowest permissible limit for the systolic pressure in hypotensive techniques, until a lower figure is proved safe.

SUMMARY

The vascular hypotension induced by sympathetic block may produce local hypoxia in the liver before other tissues are affected. This hypoxia may cause vasodepressor material to be released in the liver, producing local vasodilatation.

Observation of 17 livers during laparotomy under high epidural spinal block supported this suggestion. In 14 patients the liver appeared cyanosed at systolic pressures between 45 and 60 mm. of Hg, although tissues elsewhere were well oxygenated. In 11 the liver became turgid and rubbery to the touch at systolic pressures between 45 and 60 mm. These changes were reversed when the blood-pressure was raised by methedrine or noradrenaline.

Occult liver damage may result from this temporary hypoxia, and the systolic pressure should not be allowed to fall below 60 mm. which was found to be the critical figure for the obvious changes in this series.

I wish to thank the following surgeons for their patience and help in the observation of hepatic changes at operation: Mr. D. A. Langhorne, Mr. D. G. Martin, Mr. R. Brook, Mr. B. L. Williams, and Mr. W. S. Chapman. My thanks are also due to Mr. Nigel Cridland for his statistical advice.

EFFECT OF HYPOTENSION-PRO
DRUGS ON THE RENAL CIRCUL

J. Mackinnon
M.B. Sheff., M.R.C.P.
REGISTRAR, MEDICAL PROFESSORIAL UNIT, S
ROYAL HOSPITAL

Paton and Zaimis (1949) showed that in animals pentamethonium has a blocking act nomic ganglia, similar to that of tetraethy (T.E.A.) salts but of greater intensity an (Paton and Zaimis 1948a and b). In man T.E. a moderate fall in blood-pressure, acco tachycardia and increased blood-flow through and feet (Lyons et al. 1947). Arnold and (1949), who compared the clinical effects chloride and pentamethonium iodide (C5) in hypertensive persons, found C5 to be consid potent and to have a more prolonged action i blood-pressure and in increasing peripheral They observed postural hypotension occu $1^1/_2$ hours after its injection. These findings firmed by Burt and Graham (1950), who rapid and long-continued increase in blood-flo temperature in the lower limbs after the inj

The effective renal blood-flow is the amou in cubic centimetres per minute that circulat the functional renal tissue, measured by the or *p*-aminohippurate (P.A.H.) clearance (Gol Chasis 1944). In view of its reduction in hy and of the increasing use of C5 and other compounds in the treatment of hypertensi decided to study the effect of C5 on the renal in normal and hypertensive people. Later, the results obtained with C5, the effects o hypotensive agent—hydrazinophthalazine hyd ('prep. 5968,' Ciba), were also investigated.

Lyons et al. (1947) have shown that the effe blood-flow, as determined by the P.A.H. cleara significantly changed after the injection of T.E. normal or hypertensive people unless there is a lowering of the blood-pressure; yet Aas an (1949) reported a reduction in effective renal and glomerular filtration-rate in normal per the intravenous injection of T.E.A. bromide significant fall in the blood-pressure. It was to renal vasoconstriction.

TECHNIQUE

The renal circulation was investigated by mination of inulin and P.A.H. clearances in n hypertensive subjects.

Clearances were tested by the method of Smith et and inulin and P.A.H. were estimated by the described by Dick and Davies (1949). Urine wa through an indwelling catheter, and the bladder w out with sterile water and air at the end of each period.

TABLE I—RENAL CLEARANCES IN NORMAL PE

—	Range
In a group of 3 persons:	
Glomerular filtration-rate (ml. per min.)	122–134
Effective renal plasma-flow (ml. per min.)	646–706
Effective renal blood-flow (ml. per min.)	1218–1418
Filtration fraction	0·18–0·20
Renal resistance (absolute units) ..	5315–7[illegible]14
In a group of 14 persons:*	
Glomerular filtration-rate (ml. per min.)	119–174
Effective renal plasma-flow (ml. per min.)	540–817
Effective renal blood-flow (ml. per min.)	981–1483
Filtration fraction	0·18–0·30

* Normal values established by Davies (1951).

$$\text{Filtration fraction} = \frac{\text{Glomerular filtration-rate}}{\text{Effective renal plasma-flow}}$$

periods lasted 10–20 minutes. In all the observa- ontrol clearance periods were estimated before the njected, and at least two subsequently. All the ns were made with the person lying in bed at an out 30°.

in clearance was assumed to represent the glo- ration-rate, and that of P.A.H. the effective renal . The effective renal blood-flow was calculated fective renal plasma-flow and venous hæmatocrit. arance figure cited represents the mean of two clearance periods. The periods after the injection d from those available during the greatest hypo- onse, usually immediately after the injection of what later after the injection of prep. 5968 owing d action.

od-pressure was measured at short intervals after injection of the hypotension-producing e mean arterial blood-pressure was calculated stolic pressure plus one-third of the pulse

l resistance was calculated from the formula

$$R_k = \frac{Pm}{E.R.B.F.} \times 1332$$

ssed in absolute units as dynes cm.$^{-5}$ sec. al. 1944) where R_k = renal resistance, Pm = rial pressure, and E.R.B.F. = effective renal (ml. per sec.). The mean pressure is converted per sq. cm. by the factor of 1332.

RESULTS

nge of values for renal clearances and their in seventeen normal persons are shown in

C5 on Renal Circulation in Normal Subjects

I shows the results in two normal volunteers. l-pressure did not fall to subnormal levels in them, but in both there was a considerable fall ve renal blood-flow after injection of C5. ar filtration-rate was reduced in one case but o significant change in the other. The renal , calculated as shown above, increased in both

C5 on Renal Circulation in Patients with Benign Hypertension

gn essential hypertension a change in the renal n develops before any impairment of renal func- parent (Goldring and Chasis 1944). The early consist of a reduction in renal blood-flow with nce of a relatively normal glomerular filtration- e filtration fraction is increased. The increase esistance which occurs is thought to be produced iction of the efferent glomerular arterioles and Chasis 1944).

TABLE III—EFFECT OF C5 ON RENAL CIRCULATION IN PEOPLE WITH ESSENTIAL HYPERTENSION

Case no.	Dose and route of C5	G.F.R. (ml. per min.)	Change in G.F.R. (%)	E.R.B.F. (ml. per min.)	Change in E.R.B.F. (%)	Arterial blood-pressure (mm. Hg)	Mean arterial blood-pressure (mm. Hg)	Change in mean blood-pressure (%)	R.R.	Change in R.R. (%)
3	Before After 75 mg., I.V.	59 28	−52	572 288	−49	240/125 140/90	163 107	−35	22,854 29,692	+30
4	Before After 50 mg., I.V.	102 53	−48	500 255	−49	235/130 130/95	165 107	−36	26,479 33,145	+25
8	Before After 20 mg. subcut.	116 97	−16	801 573	−28	215/120 180/120	152 140	−8	15,222 19,629	+28

Table III shows the renal clearance in three patients with benign essential hypertension. The range of glomerular filtration-rate before injection of C5 was 59–116 ml. per minute, and of effective renal blood-flow 500–801 ml. per minute. The renal resistance varied from 15,222 to 26,479 absolute units in the three subjects.

In case 8 the hypotensive response was small. In spite of this there was a considerable fall in effective renal blood-flow. The glomerular filtration-rate was reduced to a lesser extent, and renal resistance was increased.

In the other two patients a considerable fall in blood-pressure, but not to subnormal levels, was obtained. This was accompanied by a relatively greater fall in renal blood-flow and glomerular filtration-rate, and the renal resistance was increased.

Effect of C5 on Renal Circulation in People with Malignant Hypertension

Changes in the renal circulation in patients with malignant hypertension are greater than in those with essential hypertension. There is considerable reduction both in glomerular filtration-rate and in effective renal blood-flow. The renal resistance is greatly increased.

Table IV shows the results of four observations in three people with malignant hypertension accompanied by papillœdema, retinal hæmorrhages, and exudates. They all showed gross impairment of renal function. The range of glomerular filtration-rate before injection of C5 was 29–68 ml. per minute, and of renal blood-flow 177–588 ml. per minute. The renal resistance was 26,096–77,700 absolute units.

TABLE IV—EFFECT OF C5 ON RENAL CIRCULATION IN PEOPLE WITH MALIGNANT HYPERTENSION

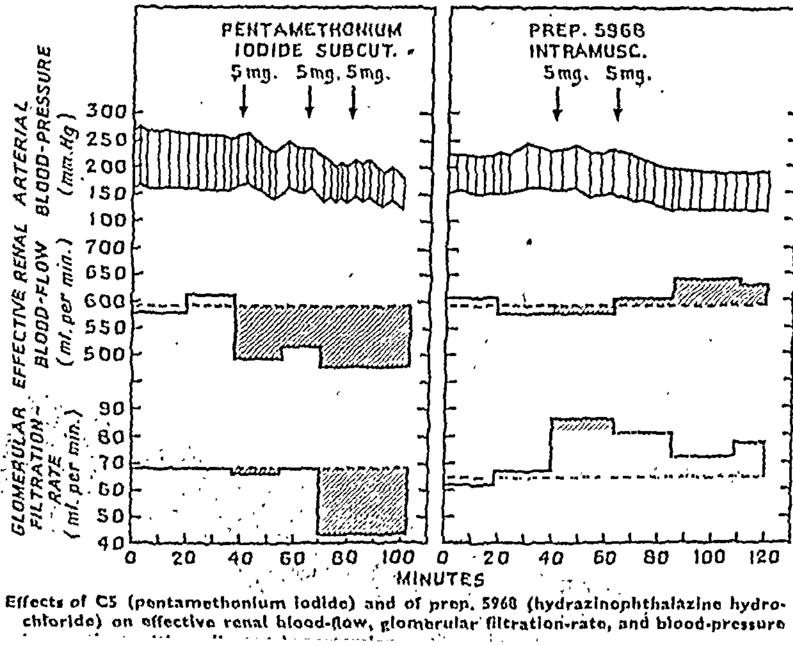
A moderate reduction in blood-pressure was obtained with C5 in each patient and this was accompanied by a fall in both effective renal blood-flow and glomerular filtration-rate. Renal resistance was increased in all except one subject in whom there was no significant change.

Results Obtained with Hydrazinophthalazine Hydrochloride

Hydrazinophthalazine hydrochloride (*prep. 5968*) is known to produce renal hyperaemia in man (Reubi 1950) and in dogs (Gross et al. 1950). Table v shows the effect of intramuscular injection of prep. 5968 in five hypertensive subjects, three of whom (cases 5, 6, and 7) had malignant hypertension. In the two people with benign essential hypertension the reduction of the blood-pressure was insignificant; and, although the doses of prep. 5968 were small, there was a considerable increase in effective renal blood-flow. The glomerular filtration-rate was increased in one case and reduced slightly in the other.

In the three patients with malignant hypertension, the reduction in blood-pressure was comparable with that obtained with C5, but in contradistinction the renal blood-flow was increased in each case. Change in the glomerular filtration-rate was inconstant, there being an increase in two cases and a reduction in the third. In all subjects receiving prep. 5968 there was a diminution in renal resistance.



Effects of C5 (pentamethonium iodide) and of prep. 5968 (hydrazinophthalazine hydrochloride) on effective renal blood-flow, glomerular filtration-rate, and blood-pressure

DISCUSSION

The accompanying figure compares the effect of C5 and prep. 5968 on the blood-pressure, effective renal blood-flow, and glomerular filtration-rate in a patient with malignant hypertension. Although the fall in blood-pressure was similar on the two occasions, the figure shows the striking contrast in the changes in the renal circulation after the drugs. The fall in effective renal blood-flow after C5 shown in the figure is representative of the change in the other subjects investigated. The rise in effective renal blood-flow after prep. 5968 in this case was small, but renal resistance diminished. The ability to produce this latter change seems to be a desirable property of drugs used in the treatment of hypertension. Thus, although there is a considerable increase in blood-flow through the limbs after injection of C5 (Arnold and Rosenheim 1949, Burt and Graham 1950), the results of the present investigation show that the visceral blood-flow is not necessarily affected in the same way. Davies (1952) has shown that cardiac output may be increased, decreased, or remain unchanged after C5, the response varying in different people; but, when there was a steep fall in blood-pressure the cardiac output fell. In both normal and hypertensive subjects the effective renal blood-flow was reduced after C5, and renal resistance was increased. The increase in renal resistance indicates that renal vasoconstriction accompanies the redistribution of blood induced by the drug. This effect of C5 on the renal circulation differs from that produced by surgi [illegible] after which the renal [illegible] cantly altered, even when the blood-pressure is reduced (Talbott et al. 1943, Foà et al. 1943).

Changes in the renal circulation analogous to those [illegible] been described [illegible] tensive and normal people (Crosley et al. 1950) and after 5-imidazoline hydrochloride ('Priscoline') in normal adults and dogs (Young et al. 1950). Both drugs increase the peripheral blood-flow through the limbs, and probably renal vasoconstriction occurred which reduced the effective renal blood-flow.

Reduction in renal blood-flow is known to follow syncope or fright and administration of adrenaline (Smith 1943). The potentiation by T.E.A. of the pressor responses to epinephrine and norepinephrine in cats has been described by St. Clair and Stone (1951), and Paton (1951) recorded adrenaline-like effects after tetraethylammonium bromide and hexamethonium. Grob and Harvey (1950) have shown that drenaline antagonises the effects of C5 on skin-temperature and blood-pressure. Possibly, therefore, adrenaline r a similar substance is responsible for the changes bserved in the renal circulation after the injection of C5.

The foregoing observations are of an acute nature and o not represent the changes in the renal circulation ccuring throughout the day in patients undergoing reatment. In one patient with malignant hypertension nd severely impaired renal function an actual increase in ffective renal blood-flow was observed after an initial ll. This took place after a very small intravenous dose f C5. But a consistent increase in effective renal blood-ow and a reduction in renal resistance were observed fter prep. 5968, thus indicating that hypotension is not n itself responsible for the renal ischæmia following the dministration of the methonium compounds.

SUMMARY

The effect of pentamethonium iodide on the renal circulation has been investigated in normal volunteers and n patients with benign essential and malignant hypertension. The glomerular filtration-rate and effective enal blood-flow are reduced by this drug. The effective enal blood-flow is reduced even when the fall in blood-ressure is small, and the reduction is greater than can e accounted for solely by a lowering of the blood-ressure. Renal resistance is increased, owing to renal asoconstriction.

In hypertensive patients the effective renal blood-flow s increased by administration of prep. 5968, and the lood-pressure is reduced. Change in glomerular filtration-rate is inconstant, and renal resistance is diminished. This seems to be a more desirable effect in the treatment of hypertension.

My thanks are due to Prof. C. H. Stuart-Harris for his constant help and advice in the preparation of this paper and for the opportunity to study his patients, and to Dr. C. E. Davies for constructive criticism. My thanks are also due to Ciba Laboratories Ltd., who supplied the prep. 5968.

". . . Writing, if not a lost art, seems at times to be a losing one. If editors have any function (and I would not disagree entirely with those who doubt it) it is that of trying to persuade authors that there is no good writing, only good rewriting—that what is worth setting down at all can be done twice as well in half the number of words—only it takes twice as long to do it. Original writing, like tapping a maple tree, is tedious business, but the really slow work, and the hard sugar, come in the boiling down of the sap."—JOSEPH GARLAND, Editor of the *New England Journal of Medicine*, *New Engl. J. Med.* 1952, 246, 801.

TREATMENT OF RHEUMATOID ARTHRITIS WITH BUTAZOLIDINE

J. P. CURRIE
M.D. Glasg., F.R.F.P.S., M.R.C.P.
OUTPATIENT PHYSICIAN, GLASGOW ROYAL INFIRMARY

This paper records the effects of a new drug, butazolidine, on 81 patients with rheumatoid arthritis.

INTRODUCTION

The comparative efficacy of amidopyrine in relieving pain in rheumatoid arthritis and other "rheumatic" conditions has been commented upon since its introduction in 1884. Many workers, notably on the Continent, have described its apparent success in relieving rheumatic pain where salicylates, phenacetin, and other analgesics have failed.

The introduction of an injectable form of amidopyrine ('Irgapyrin') was followed by reports of the considerable relief from pain that it gave during acute exacerbations of rheumatoid arthritis. The use of irgapyrin in the clinic at Glasgow Royal Infirmary corroborated these observations, but it was thought that the relief obtained from this preparation was out of all proportion to the amount of amidopyrine given, and it was found that oral administration of amidopyrine, in doses sufficient to produce a similar blood concentration, did not give comparable symptomatic relief. Moreover, after daily injections of irgapyrin, many of the joint swellings were somewhat reduced—a benefit not conferred by oral amidopyrine.

The solvent used for the amidopyrine in irgapyrin is a pyrazolidine derivative, 1 : 2-diphenyl-3 : 5-dioxo-4-*n*-butylpyrazolidine (G 13871 or butazolidine). The pharmacology of this substance has already been investigated by Wilhelmi (1949), who showed that in laboratory animals it acted as a mild analgesic, a moderately powerful antihistaminic, an antiphlogistic, and an antipyretic. Pulver (1950) found that, although there is a close structural relationship between butazolidine and amidopyrine, their behaviour in the animal body is different; amidopyrine is rapidly converted into inactive decomposition products, while butazolidine is only slowly broken down and excreted.

So far as can be ascertained, the analgesic properties of butazolidine alone have not been investigated, and, since its toxicity has been shown to be low, it was decided to give this drug to a series of patients in the acute phase of rheumatoid arthritis.

METHOD AND RESULTS

All the patients selected for treatment fulfilled the following diagnostic criteria for rheumatoid arthritis: (1) acceptable clinical history and picture; (2) polyarthritis; (3) radiological confirmation, or lack of evidence of other joint disease; (4) normal blood-uric-acid level; (5) negative Wassermann and Kahn reactions; (6) negative Widal reaction for abortus fever; (7) negative gonococcal complement-fixation test; and (8) raised erythrocyte-sedimentation rate (E.S.R.) and reduced plasma viscosity. They were all suffering from acute exacerbations at the time of treatment.

The following subjective and objective tests of improvement were used:

Subjective

(1) Pain and tenderness.
(2) Performance:
  Dynamometer readings for power of grip.
  Range of movement voluntarily performed with affected joints.
  Time taken for performance of standard exercises.
(3) Well-being.

Objective

(1) Joint measurements.
(2) E.S.R. and plasma viscosity.
(3) Appearance of joints.

TABLE I—RESULTS AFTER 10 DAYS' TREATMENT

Treatment	No. of cases	Symptomatic		Performance		Objective	
		Improvement	Relapse	Improvement	Relapse	Improvement	Relapse
Butazolidine	41	40 *(97·6%)*	0	40 *(97·6%)*	0	10 *(24·4%)*	0
Saline	40	9 *(22·5%)*	1 *(2·5%)*	8 *(20%)*	0	0	0

The patients were given either daily intramuscular injections of 1·0 g. of butazolidine as a 20% solution, or injections of sterile normal saline. In each case treatment was given for ten days. Treatment was then changed without the patients' knowledge; those previously having butazolidine were given sterile saline and vice versa.

The interphalangeal joints were measured by the 'Wheatsheaf' ring method (Hart and Clark 1951), and the larger joints by ringing them with indelible ink and applying a tape-measure round the ring. It follows that the assessment of improvement in joint swelling was easy in the fingers and very difficult in the larger joints. As has been indicated elsewhere (Currie and Will 1950), variations of up to 0·5 cm. may arise from experimental error, and therefore any changes of less than 0·5 cm. were not regarded as significant. The cases were assessed before treatment, after ten days' treatment, and at the end of twenty days' treatment.

Tables I–III show the results in 81 patients.

DISCUSSION

The difficulties of assessing improvement in rheumatoid arthritis are well known. Efforts were made to "control" this clinical trial of butazolidine by ensuring that patients did not know when they were receiving butazolidine and when saline. The injections of butazolidine usually caused local pain, and care was taken to inject enough saline, when this was being given, to give at least some discomfort at the site of injection.

TABLE III—EFFECT OF TREATMENT ON E.S.R. AND JOINT SWELLING WHERE THESE WERE AFFECTED

Treatment	No. of cases showing								
	Reduction in E.S.R.			Reduction in swelling of large joints			Reduction in total ring count for all 10 fingers		
	1–10 mm. per hr.	11–20 mm. per hr.	Over 20 mm. per hr.	Slight	Moderate	Marked	5–10 sizes	11–15 sizes	Over 15 sizes
Butazolidine..	3 *(7·3%)*	7 *(17·1%)*	0	0	4 *(9·7%)*	6 *(14·6%)*	1	3	1
Butazolidine followed by saline	2 *(4·9%)*	5 *(12·2%)*	0	4 *(9·7%)*	3 *(7·3%)*	0	3	1	0
Saline followed by butazolidine	6 *(15%)*	4 *(10%)*	2 *(5%)*	0	7 *(17·5%)*	7 *(17·5%)*	2	5	1

Of the 81 patients treated with butazolidine, 77 said that their symptoms were relieved—i.e., that their pain was less and that their joints moved more easily. Only 24, however, showed measurable evidence of improvement. All the patients who showed objective signs of improvement also reported subjective improvement. The importance of recognising the subjective nature of performance tests seems to be well shown in the tables. Generally, when a patient feels better he performs better. The number of patients showing objective improvement during this short test seems significantly high; for, while some 30% of patients suffering from rheumatoid arthritis will show spontaneous remission or temporary arrest of the disease over a period of some months, it is difficult to believe that 30% would do so within the three weeks of this trial. Of these 24 patients wit objective improvement, 4 have remained both objectivel and subjectively better (for sixteen, fourteen, eleven, or eight weeks respectively), 11 relapsed within three „ and 9 within twenty weeks.

These limited trials suggest that butazolidine doe produce a marked degree of symptomatic relief i acute exacerbations of rheumatoid arthritis. Moreove the drug seems to have some antirheumatic propert which can reduce periarticular swelling, tenderness, an œdema.

During the administration of the drug, no electrolyt shift was observed in any patient nor was there an evidence of fluid retention or diuresis. The eosinophi count was unaffected, and, in 5 patients whose 17 keto steroid excretion was measured, no significant chang was noted. These investigations were made becaus the benefit given by any drug in rheumatoid arthritis i often suggested to be connected with cortisone or adreno corticotropic hormone activity, but this does not seem t be the case here. Wilhelmi (1951, 1952), however, note a big fall in the eosinophil-count after giving the drug t rats, and he believed that adrenocortical stimulation ma follow the use of butazolidine.

TABLE II—RESULTS AFTER 20 DAYS' TREATMENT

Treatment	No. of cases	Symptomatic		Performance		Objective	
		Improvement	Relapse	Improvement	Relapse	Improvement	Relapse
Butazolidine followed by saline	41	34 *(82·9%)*	6 *(14·6%)*	32 *(78%)*	5 *(12·2%)*	7 *(17·1%)*	0
Saline followed by butazolidine	40	37 *(92·5%)*	0	37 *(92·5%)*	0	14 *(35%)*	0

The drug cannot be just an analgesic, because tha would hardly explain a fall in E.S.R. and a reduction i the joint swelling. Further, when test-doses were give in cases of cephalgia, neuralgia, postoperative pain, pai from trauma, &c., the drug compared poorly with ful doses of aspirin. I have no hesitation in claiming, however, that, as an anodyne in cases of rheumatoid arthritis, butazolidine is quite exceptionally effective.

My thanks are due to Dr. J. W. Macfarlane for placing bed at my disposal while carrying out these trials, and to Pharma ceutical Laboratories Geigy Ltd. for their help and for supplie of butazolidine.

BENEMID IN THE TREATMENT OF STREPTOCOCCAL ENDOCARDITIS

G. P. BAKER
M.D. Camb., M.R.C.P.

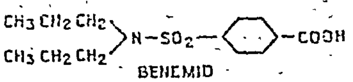
THOMAS PILKINGTON
M.D. Lond., M.R.C.P.

MEDICAL FIRST ASSISTANTS, ST. GEORGE'S HOSPITAL, LONDON

IN a small proportion of cases of subacute bacterial endocarditis the causal organism is highly resistant to penicillin; usually it is a non-hæmolytic *Streptococcus fæcalis* of Lancefield's group D (Robbins and Tompsett 1951). Various antibiotics have been recommended for these resistant cases, but hitherto none has been completely satisfactory. Aureomycin and chloramphenicol have been disappointing; but some patients have been cured with streptomycin, alone or in combination with penicillin (Hunter 1947, Cates et al. 1951), and others have responded to high blood-penicillin levels achieved with the aid of caronamide (Boger et al. 1947, Stuart-Harris et al. 1949).

We report here a case of *Strep. fæcalis* endocarditis treated successfully with large doses of penicillin together with 'Benemid,' a new compound introduced by Boger et al. (1950). Benemid (Sharp & Dohme) is p-(di-n-propylsulphamyl) benzoic acid, and, like caronamide, it temporarily blocks excretion by the renal tubules of such substances as penicillin, p-aminosalicylic acid, and phenolsulphonephthalein. The dose suggested is 0·5 g. six-hourly (2 g. daily), which is much less than the caronamide needed for a similar effect (18–24 g. daily). From the data published benemid seems to have fewer side-effects than caronamide; in particular, there is less nausea and vomiting (Boger and Crosson 1950, Boger et al. 1950). Benemid was first used in this country by Walker and Hunter (1951). The chemical formulæ of the two substances are shown below:

CARONAMIDE



BENEMID

CASE-RECORD

A R.A.F. fighter-pilot, aged 30, was in perfect health until December, 1949, when he suddenly complained of slurring of speech, which rapidly cleared up. This was followed by malaise, pyrexia, and various aches and pains. In February, 1950, he was diagnosed as having rheumatic fever, and he was treated at home with salicylates for two months. In April, 1950, he was admitted to another hospital, where subacute bacterial endocarditis was diagnosed (positive blood-culture), and he was treated with large doses of penicillin and streptomycin, both separately and together (for details see table I). He made an apparent recovery and was discharged in August, 1950.

On admission to St. George's Hospital in September, 1950, he was pyrexial, and there was a loud rough systolic murmur at the apex. A fading Osler's node was present on the left palm. The spleen was not palpable, no red cells were found in the urine, and there was no clubbing of the fingers. Blood-cultures were persistently positive, and *Strep. fæcalis* (group D) was grown from each of them.

TABLE I—DETAILED SUMMARY OF TREATMENT AND FINDINGS

Dates	No. of days	Drug	Dosage		Blood-cultures	Clinical findings
			Daily	Total		
1950 April 17–June 6	51	Penicillin	4–8 mega units	308 mega units	May 6 : sterile	Feeling very well, apyrexial
June 7–June 24	18	Streptomycin	2 g.	34 g.	June 22 : positive	Normal pulse-rate
,, 25–Aug. 6	43	Penicillin	10 mega units	430 mega units	July 5 : sterile	..
July 1–July 31	31	Streptomycin	3 g.	93 g.	,, 12 : sterile	Relapse after 2 weeks without treatment
					From Sept. 10 to 14 : positive	12 cultures were made; 11 were positive and grew *Strep. fæcalis* group D
Sept. 15–Nov. 17	64	Aureomycin	6 g.	384 g.	Oct. 7 : positive	Feeling very well, except for nausea during last two weeks of aureomycin course; apyrexial; normal pulse-rate
Nov. 18–Dec. 1	14	Penicillin (six-hourly)	20 mega units	280 mega units	..	..
1951					Jan. 12 : positive	Relapse after 3 weeks without treatment
Jan. 17–March 7	50	Aureomycin and chloramphenicol (six-hourly)	2 g. āā	100 g. āā	..	Feeling well, apyrexial; normal pulse-rate
March 8–April 10	Patient taking drugs on alternate weeks only as out-patient	Aureomycin and chloramphenicol	2 g. āā	28 g. āā	..	..
					April 11 : positive	Relapse during 4th week and while not taking drugs
April 11–May 2	22	Aureomycin and chloramphenicol	2 g. āā	44 g. āā	April 25 : positive	Feeling very well, painful embolus in finger on April 16
May 3–June 27	56	Penicillin (six-hourly)	20 mega units	1120 mega units	May 17 : sterile	Feeling very well
		Streptomycin	2 g.	112 g.	June 31 : positive	Relapse 3 days after discontinuing therapy
July 5–10 ..	6	Sulphadiazine	(Usual course)	35 g.	July 5 : positive	General malaise, tachycardia, and pyrexia showed that bacteræmia was not controlled; fresh petechiæ regularly
July 11–25 ..	15	Terramycin	3 g.	45 g.	July 17 : positive	
July 26–30 ..	5	Aureomycin and chloramphenicol	2 g. āā	10 g. āā	..	Symptoms controlled, but petechiæ still appearing
Final course July 31–Sept. 27	59 3 56	Benemid six-hourly and penicillin three-hourly	4 g. 20 mega units } 32 mega units }	236 g. 1852 mega units	Aug. 11 : sterile	Feeling very well; petechiæ gone
					Oct. 1 : sterile ,, 2 : sterile ,, 4 : sterile ,, 6 : sterile	Well and working nine months later

TABLE II—HOURLY BLOOD-PENICILLIN LEVELS ACHIEVED WITH THE AID OF BENEMID

Treatment		Blood-penicillin level (units per ml.)			Remarks
Benemid (g.) six-hourly	Penicillin (mega units) three-hourly	1st hr.	2nd hr.	3rd hr.	
1	2½	64·0 25·6	16·0 12·8	16·0 12·8	Blood-urea level 28 mg. per 100 ml., no casts, no albumin
	4	128·0 ..	64·0 32·0	64·0 32·0	

Cardioscopy showed slight left-ventricular enlargement, with systolic expansion to the left auricle. Electrocardiography showed partial right bundle-branch block. The patient's general physical condition was surprisingly good in spite of his long illness, and he was not anæmic (Hb 91%).

Treatment.—Qualitative estimation of the sensitivity of the streptococcus to antibiotics showed that it was highly resistant to penicillin and streptomycin, but very sensitive to aureomycin and to chloramphenicol. The patient was accordingly treated with a large dose of aureomycin (6 g. daily in divided doses for sixty-four days); yet even in the middle of this course a blood-culture was positive. He was later treated with courses of penicillin, streptomycin, aureomycin, chloramphenicol, terramycin, and sulphadiazine, either alone or in various combinations (table I); but the symptoms of bacteræmia were merely suppressed, and he promptly relapsed a few days after each course of treatment. In July, 1951, the streptococcus was found to resist the following drugs up to the following levels:

Penicillin	2·5 units per ml.
Streptomycin	25·0 μg. per ml.
Chloramphenicol	0·5 μg. per ml.
Aureomycin	0·125 μg. per ml.
Terramycin	1·0 μg. per ml.

Finally the patient was treated with penicillin 4 mega units three-hourly (32 mega units daily) and benemid 1 g. six-hourly (4 g. daily) for fifty-nine days. No toxic effects, apart from slight abdominal discomfort, were noted with this dosage of benemid, although it was twice as large as that used by Boger et al. (1950). During this treatment sufficient penicillin was excreted in the urine to reduce Benedict's reagent. The very high blood-penicillin levels achieved are shown in table II, which also shows that there was no evidence of renal damage.

Progress and Follow-up.—During treatment and subsequently, the patient remained apyrexial and blood-cultures were negative. He is now, nine months later, apparently perfectly fit and is working. His cardiac signs remain unchanged, but there is no functional impairment.

DISCUSSION

In this case the causal streptococcus was sensitive in vitro to aureomycin and chloramphenicol, but these antibiotics did not eradicate the infection. The streptococcus was relatively insensitive to penicillin, but the very high blood-penicillin levels achieved with the aid of benemid were sufficient to arrest the disease permanently. This observation is consistent with the view that penicillin is bactericidal, whereas the other antibiotics used are only bacteriostatic.

The scheme of treatment recommended by Cates et al. (1951), using penicillin and streptomycin together, has the disadvantage that large doses of streptomycin may damage the inner ear; and it seems that in combating micro-organisms with a high resistance to penicillin, the use of benemid to raise the blood-penicillin level may be the best course.

SUMMARY

A case of *Strep. fæcalis* endocarditis is described.

It did not respond to large and long-continued dosage with penicillin, streptomycin, aureomycin, and chloramphenicol.

Complete cure appears to have resulted from the high blood-penicillin levels achieved with the aid benemid.

Our thanks are due to Dr. Kenneth Robson, under care the patient was admitted, for permission to and to Dr. Stephen Elek for numerous bac examinations. We are indebted to Dr. William P. director of the medical division of Sharp & Dohme for supplies of benemid; and to Dr. M. M. Nagley, of Park Hospital, who gave us some of his own very limit supplies.

HÆMATURIA FROM AN UNDETECTED URACHAL TUMOUR

R. CAMPBELL BEGG
M.D. Edin., M.Sc. N.Z., F.R.C.S.E., F.R.A.C.S.
OF JOHANNESBURG, SOUTH AFRICA

SURROUNDED by muscle and resting on the mucosa without penetrating it, the walnut-sized conoidal mass bled from time to time into the urachal canal which traversed it. Being a transitional-celled carcinoma, devoid of the usual goblet cells, it produced no "jelly" in the urine to betray its presence. The vesical outlet of the urachus, minute and concealed by a mucosal fold, eluded discovery during seven cystoscopies, and was revealed at the eighth only by the stalactite of blood-clot which depended from it. The diagnosis was delayed for five years. The extenuating circumstances of this humiliating lag may be judged from the following story.

CASE-REPORT

Mr. A was a robust man of 73. He owned two farms remote from Johannesburg, one on either side, and he secured his medical advice in instalments as he passed through the city from one to the other. His boyhood had been marred by two years of terminal hæmaturia from the prevailing bilharzia, but it was fifty years later that he again passed "pure blood." The attack was accompanied by frequency, urgency, and strangury. This he endured for four weeks on his Zeerust farm before coming to Johannesburg for advice and relief. The consultation took place on Oct. 29, 1945. The gross hæmorrhage had ceased, but the urine contained a heavy sediment of red and white cells and bacteria. A few days' treatment ameliorated the inflammation, and a satisfactory investigation was carried out; but it disclosed no abnormality in the urinary tract with the exception of an early trilobed hypertrophy of the prostate. It was concluded that the bleeding had been caused by an intense cystitis originating in a prostatitis or even in the rupture of a small abscess in the gland.

Twelve months passed without further incident, and a routine examination, including cystoscopy and pyelography, gave the same negative results. The prostate was causing no trouble and there was no residual urine at all. It was not until April, 1950, nearly five years after the original attack, that the bleeding began again. As before, there was an inflammatory element, but it was overshadowed by the hæmaturia, which was at times alarming though not sustained. Repeated cystoscopies failed to locate the bleeding, which was invariably in abeyance at the times of examination. Always the ureteric effluxes were clear, the urine drawn from each kidney free from blood, and the pyelograms, intravenous and retrograde, normal. In the fruitless search of the whole bladder mucosa, the vault received special attention; for the possibility of an invading urachal tumour was by no means overlooked.

In the intervening five years the prostate had not increased in size. It was no hindrance to diagnosis; for it did not revent catheters being passed into the ureters. This point is mentioned because it is sometimes necessary to do a prostatectomy to find the site of hæmorrhage in the upper urinary tract. Most urologists have learnt, often by the hard way, that even grossly hypertrophied prostates are, as a rule, incidental to, and not the cause of, massive hæmaturia. In this patient there was very little excuse for interfering with the gland. Operation was a counsel of despair, given when he demanded action. I had no real conviction that the prostate could cause the hæmorrhage; but, after all, no other abnormality could be found, and adenomatous prostates do bleed! Be that as it may, the operation was advised and carried out—an easy and uneventful enucleation. Pathologically the specimen was an adenoma with some round-cell infiltration but no malignancy. The route chosen was the suprapubic one, correct enough in ordinary circumstances but faulty in this case, because the incisions in the abdominal wall and bladder were transverse—according to my usual practice. Thus the vesical apex remained above the field, and the growth perched on it was by-passed. It was so mobile that the palpating finger, even through the open bladder, felt no thickening or resistance.

Wisdom after the event, and possibly more versatility before it, would have insisted that a longitudinal incision, while not prejudicial to the prostatectomy, was imperative for the discovery and removal of any lurking urachal growth.

Nemesis followed quickly on the heels of this hit-or-miss surgery. All seemed well. The urine remained clear after the first few postoperative days. Exactly two weeks after the operation, the grateful and happy patient said goodbye to the ward staff, went to his hotel, and started to bleed that very night! When he was readmitted the following morning, the urine was again clear and cystoscopy profitless. Six days later he was discharged once more only to undergo the same tantalising sequence of events. The next cystoscopy disclosed a clot of unknown origin lying in the bladder. After it was removed the irrigating fluid returned absolutely clear. The prostatic cavity was completely epithelialised. There was one new finding—a tiny patch of telangiectasis on the vault—but its significance was not appreciated. The diagnostic drama, with anxious patient and baffled surgeon, was, however, drawing towards its climax. It was clear that not even a logical guess could be made until the bleeding was actually seen. The patient waited in his hotel while arrangements were made for cystoscopy at any hour of the day or night. The moment bleeding began he must send the signal and immediately follow it in person, in office hours to the surgery, at other times to the nursing-home. These clear-the-line tactics succeeded. Thirteen days later, and six weeks after his prostatectomy, the call came through at 2.30 in the afternoon. At 3 o'clock, with the cytoscope in the bladder, I was watching the drops of blood falling from the lower end of a thin festoon of clot hanging from the vault just behind the telangiectatic patch. The latter, as it now appeared, was the herald of a malignant invasion on its way towards the vesical aspect of the mucosa. Strangely enough and for the first time, there was some tenderness on deep pressure behind the symphysis pubis. It was as if Nature, tired of concealment, was liberally giving up the carefully guarded secret. Next day I carried out my radical operation for urachal tumours (Begg 1931). This was Sept. 21, 1950. Section of the specimen showed no involvement of the vesical aspect of the mucosa.

Mr. A died suddenly of coronary disease in March, 1952, just eighteen months after the last operation. He was then 81. I examined him a few months before his death. There had been no bleeding. The urine was microscopically clear; bladder function was normal; and clinically and radiologically there was no evidence of metastases.

CONCLUSIONS

Some conclusions may be drawn from this story.

A urachal tumour may cause hæmaturia, even though there is no clinical or cystoscopic evidence of its presence. The blood passes down the terminal urachal canal which in a high proportion of normal people communicates with the bladder cavity.

Such a tumour can only be diagnosed if blood is seen to drip from the bladder vault. Only under exceptionally favourable conditions can bleeding be seen. If it is known that the blood comes from the bladder and not from the upper urinary tract, it may be permissible to make a small suprapubic incision to palpate the bladder apex.

Elderly men with gross hæmaturia often have adenomatous prostates. These are rarely the cause of the bleeding, but should it be decided that a prostatectomy is advisable, the operation should be done in such a way that the apex of the bladder is exposed and a urachal tumour may be discovered.

Medical Societies

BRITISH TUBERCULOSIS ASSOCIATION

Isoniazid in Pulmonary Tuberculosis

Five or six years ago, as Dr. Andrew Morland reminded this association at its annual conference held at Cambridge last week, we had no drugs which touched the tubercle bacillus. Now we have some formidable ones, and each newcomer will have to be proved against the best performance of its forerunners. It was therefore natural that the first session, with Sir Geoffrey Todd, the president, in the chair, should be devoted to the results so far achieved with isonicotinic acid hydrazide—referred to variously as INAH, I.N.A.H., I.N.H., and isoniazid.

THE DRUG AND ITS PROPERTIES

Prof. Robert Cruickshank said that the antituberculous properties of isoniazid were discovered at about the same time by the experimental chemists of three firms, Roche, Squibb, and Bayer; and, since it is easy and cheap to make, a flood of preparations have now been released. The tubercle bacillus, in its waxy coat, multiplying relatively slowly, and almost certainly able to multiply within the macrophages, can live for years in the necrotic centre of the tubercle, protected by the fibrous wall; and it thus presents a special problem to pharmacology. As long ago as 1932 we were saying that we must consider what drugs would penetrate both the tubercle and the wall of the macrophage.

Recent methods have made it easier to study the action of drugs. The new medium, ‘Tween-albumen” allows the tubercle bacillus to grow easily and diffusely; Sir Howard Florey and his colleagues at Oxford have devised a beautiful technique by which a tubercle on a rabbit's ear can be watched minutely, and the effect of drugs directly observed; while in the same laboratory a technique has been devised by Dr. G. B. Mackeness for keeping macrophages alive in nutrient medium for three weeks, and studying the intracellular as well as the extracellular action of drugs on tubercle bacilli which the cells have ingested. This last method, Professor Cruickshank said, may make the use of animals unnecessary for drug studies on tuberculosis.

Isoniazid has proved to be highly specific, acting on acid-fast bacilli and otherwise only on some fungi. It is more effective against virulent tubercle bacilli than against those which are less virulent, and its action is not affected by resistance of the bacillus to streptomycin or *p*-aminosalicylic acid (P.A.S.). We do not know yet whether it is bactericidal; but this must be decided, for recent work on combined therapy shows that while two bactericidal drugs given together may reinforce each *other's action*, a bactericidal drug and a bacteriostatic drug may be antagonistic. Mackeness has shown that isoniazid is as active inside the phagocyte as outside, and acts in very low concentration. Streptomycin is less active inside than outside the cell; terramycin is equally active in both; while P.A.S. has almost no action inside the cell. Experimentally, isoniazid, when given early, has been effective in the treatment of tuberculosis in mice, guineapigs, and rabbits: but in these animals the disease relapsed when the drug was stopped. It has also proved effective in animals infected intracranially with tuberculosis. But it seems that almost any culture of virulent tubercle bacilli contains some naturally resistant strains, especially when grown for more than two weeks in a liquid medium; and the resistance of strains increases rapidly. We need to know whether the virulence of these mutants is the same as that of the parent strain, and how quickly they will revert to non-resistant strains when the drug is withdrawn.

Pharmacologically, isoniazid is almost perfect—easily prepared, stable, possible to autoclave, quickly absorbed (reaching a peak in the blood in $^{1}/_{2}$–1 hour), causing little intestinal disturbance, and readily diffusible, even into the cerebrospinal fluid. Some 45–70% is excreted in the urine in 24 hours, and a further percentage in the fæces and saliva. At least ten times the effective dose can be attained in the blood within an hour, and, since it stays at an effective level for 12 hours, two doses daily are sufficient. The level in the C.S.F. is as high as in the blood. Liver damage and some excitation of the central nervous system have been seen as toxic effects in animals.

EARLY CLINICAL EXPERIENCE

Dr. **Morland** discussed experience with isoniazid at the Seaview Hospital, New York, which he visited in April. This vast hospital of 12,000–15,000 beds receives mainly cases regarded as hopeless. A group of 44 patients with bilateral caseous disease of the pneumonic type were selected for treatment; all were febrile and going downhill, and all were resistant to streptomycin. They were treated with isoniazid only; their temperatures fell to normal, and there was an average gain of 19 lb. in weight among them over 15 weeks. Their appetites became ravenous, they lost their apathy and became euphoric, and the number of tubercle bacilli in their sputa was much reduced. But cavity closure was not common, and the erythrocyte-sedimentation rate (E.S.R.) was little affected. There was some insomnia, but no serious injuries such as liver damage. The isopropyl derivative of the drug gave much the same results as the acid hydrazide, but was a little more toxic. Dr. Morland was told that there was no evidence of drug-resistance at Seaview, but this is not the opinion of other American centres. The gain in weight stopped when patients reached their maximum normal weight. Chronic cases did not improve to the same extent as acute cases, and 2 patients became respiratory cripples because the lung parenchyma left to them was not sufficient to meet the demands of their increased energy. Dr. Morland pointed out that some gain in weight and improvement in well-being may always be expected when P.A.S. is stopped, because, good as it is, P.A.S. is no stimulant to appetite.

He has himself given isoniazid, in daily doses of 2–4 mg. per kg. body-weight, to 40–50 patients, and has seen no toxic effects, not even insomnia or nervousness. Some gained up to 2 st. in weight, others showed little change. It is not known whether or not the increased appetite is due to a specific action on the tubercle bacilli or to some other cause; but he has lately given the drug to a girl with anorexia nervosa with benefit to her weight and appetite. He has seen rapid healing of tuberculous ulceration of the larynx with isoniazid, and one case of a streptomycin-resistant ulcer of the tongue and larynx which healed in 2 weeks. He has also seen the drug check the downward course in 6 out of 7 advanced chronic cases; but how lasting, he asked, will this effect be? He thinks the drug *may* be as effective as streptomycin given with P.A.S., but he doubts it. On the other hand it is pleasant to take and it produces euphoria, which means much for the patient with deteriorating disease.

Dr. E. G. **Sita-Lumsden** has visited centres in o parts of the United States, as well as Seaview, confirmed that no serious toxic results have been there, though some patients have shown eu nervousness, twitching, and occasionally dryness of mouth, postural hypotension, fall in hæmoglobin centration, eosinophilia, and transient albuminuria. severe liver damage has been seen in man. Reports now coming in of delayed improvement, with [illegible] of cavities, after 5–6 months of treatment. The seems to have about the same activity in acute culosis as streptomycin, though it is less predictable its results. The more acute the disease, the more the response: fever may even terminate by crisis. acute pneumonic disease the cough is usually gone the end of the second week, and sputum decreases much that by the end of the third week it may be di to get any for testing. The clinical and sub changes, however, are much more immediate impressive than radiological changes, which are slo and less certain. Fluid levels in cavities may dry out, in 3 of Dr. Sita-Lumsden's patients fluid levels ap during treatment. He thinks isoniazid alone is prob not quite so good as streptomycin with P.A.S., isoniazid and streptomycin together will probably better. He has known isoniazid produce reco without relapse or meningitic spread, in 6 cases of a miliary tuberculosis. Resistant strains may develop rapidly, and probably 60–80% of patients will b resistant after 3 months; but resistance may soon lost, for artificially induced resistance in B.C.G. is quickly lost by back-mutation. It may thus be useful to give courses lasting 6–8 weeks. His experience with 65 cases has borne out these generalisations: the general pic of improved appetite, reduced sputum, and gain in weight was there, with some improvement, great or little, in the X-ray findings in nearly half the cases. He noted that while under treatment 7 patients had hæmoptysis for the first time. He concluded that isoniazid is no mere appetiser but a powerful drug of the same order as streptomycin given alone.

INVESTIGATIONS IN PROGRESS

Dr. **Marc Daniels** told the meeting that the largest coöperative clinical investigation ever undertaken by the Medical Research Council is now in progress on this drug. Some 38 hospitals in various regions of the United Kingdom, and half the chest services of the country, are taking part in it. The chest clinics are providing acute cases and the hospitals intermediate and chronic cases and studies are being made of streptomycin and P.A.S. (for comparison), isoniazid alone, and streptomycin combined with isoniazid. Results are being analysed as they come in, so that significant findings can be published at once.

Dr. C. W. **Bartley** reported a series of 67 cases treated, at the London Hospital, on isoniazid alone. At first 2–4 mg. per kg. body-weight was given, and later 5–7 mg. There was no toxicity worth talking about. In 1 patient, with tuberculous endometritis, there was constipation for 9 days, and 2 had albuminuria (but one of these already had nephritis and the other a tuberculous kidney). Several patients showed an immediate reaction in the form of a brisk febrile response, increased cough, and tightness of the chest, lasting a few days, but this was followed by fall of temperature to normal levels, and general improvement on the lines already described. Hæmoptysis was a fairly common complication, being seen in 13 cases. Several cases behaved memorably. Thus a cavity which had been full for 10 years emptied in 10 days; two tension cavities in a girl of 15 closed in a few weeks; an untreatable case with 11 years' history gained $1^{1}/_{2}$ st. and closed one cavity in 6 weeks, and showed much thinning of the wall of another. Dr.

Bartley thought isoniazid an extremely effective drug even by itself, but there was strong clinical evidence that resistant strains may emerge after 8–12 weeks.

Dr. **J. W. Craig** has treated with isoniazid 55 cases aged 45 and over, and 50 cases under 45. They had all been treated by other methods for more than 2 years. What struck him forcibly was the reduction, after 6 weeks, of the total weekly sputum of the group by 12 pints. Moreover 65 became sputum-negative. The gain in weight, he found, was much greater in the younger patients.

Dr. **E. K. Pritchard** reported a controlled trial at Guy's Hospital. All were advanced bilateral cases in which other methods had failed. After 4 weeks the examining physicians, who did not know which were the treated patients and which the controls, were able to discriminate between them on the clinical findings. The weight of the treated cases was up, their temperatures and their E.S.R.s were down, their appetites were increased, and their euphoria evident.

Prof. **Robert Knox**, whose department has undertaken the bacteriological side of the Guy's study, noted that there was a rapid drop in the sputum count in patients on isoniazid, followed by a slow rise. Resistance to the drug is developing so far in 3 patients. In vitro, combination with streptomycin seems to increase the effectiveness of isoniazid; and patients on both isoniazid and streptomycin are also being investigated bacteriologically. Referring to Professor Cruickshank's remarks on its ready diffusibility, Professor Knox drew attention to its low molecular weight.

Dr. **Peter Edwards** reported from his series moderate gains in weight, and a sputum conversion-rate of 69%, with no complications. He mentioned that 16 control cases given lactose also felt well and put on weight for 4 weeks; but after that their improvement ceased, whereas among patients on isoniazid it continued.

Dr. **Tanner**, visiting from Switzerland, said that in his 100 cases he is beginning, after 2 months, to find improvement in cases which earlier showed no change. Though cavities sometimes enlarged, the walls of them thinned during treatment with isoniazid, and thus allowed better access to other drugs. He has had 3 cases of hæmoptysis but no other serious complication.

ROYAL SOCIETY OF MEDICINE

Treatment of Anuria

The section of urology of the Royal Society of Medicine met on June 26 under the chairmanship of Mr. **A. H. Jacobs**, the section's president, to discuss the treatment of anuria.

Dr. **E. M. Darmady**'s opening remarks referred to the improved prognosis in the anurias since he last addressed the section four years ago. This he attributed to better understanding of the pathology and natural history of these conditions with consequent improvement in treatment. Referring particularly to the syndrome of acute tubular necrosis, he suggested that renal circulatory embarrassment was of paramount importance in ætiology and that eight hours was a critical time for the human kidney to remain severely ischæmic. Nephron dissections by Oliver and by his own group had shown that, whatever the ætiology of the tubular necrosis, there was a characteristic pathological lesion consisting of patchy epithelial degeneration and areas of basement-membrane disruption affecting the whole tubule. The natural history of the disease had been described by Bull and his colleagues. In the precipitating phase there was usually renal circulatory disturbance due to a wide variety of causes. This was succeeded by a period of anuria or severe oliguria, and this in turn by a period of diuresis characterised by excessive loss of water and electrolytes.

As regards treatment, he referred to the possible use in the onset phase of osmotic diuretics (e.g., intravenous sodium sulphate) where hæmoglobin or other nephrotoxic substances were being excreted, and to measures that might restore renal blood-flow (e.g., caudal anæsthesia in obstetric anurias or blood-transfusion in oligæmic shock). As regards management of the anuric phase, there had been a swing away from the use of dialysis methods in favour of conservative treatment. There was considerable difficulty in assessing the state of cellular and extracellular hydration of these patients, and such simple procedures as hæmatocrit readings could be misleading. Hamburger had recently championed the so-called "effective osmotic pressure" (determined by the freezing-point of the plasma with allowance for the osmotic pressure of urea which is freely diffusible), and this could be a useful guide to treatment. Simple methods of estimating total body water and extracellular water were urgently needed. In the phase of excessive diuresis standard solutions containing potassium should be readily available—e.g., 1·9% potassium lactate or 1·1% potassium chloride solutions.

Dr. **G. M. Bull** said that the experience of the Hammersmith group had been largely with anuria due to circulatory renal insufficiency (extrarenal uræmia) or to acute tubular necrosis. In a five-year period, 48 patients were seen who were classified in the first group and 47 in the second group. Less common causes of anuria were nephritis and malignant hypertension. Obstructive anurias would naturally be referred directly to surgical units; and in his medical unit, of 112 anuric subjects only 6 were so classified. The commonest cause of circulatory renal insufficiency was oligæmic shock, but it might occur in heart-failure. Renal vasoconstriction compensating for inadequacy of the general circulation led to renal dysfunction with increasing blood-urea levels. If the general circulation were not restored to normal within a critical time, which varied with the severity of the renal vasoconstriction, then renal damage —i.e., acute tubular necrosis—would result. In any uræmic patient, then, such extrarenal factors as dehydration and cardiac failure must be sought and corrected, whether they occurred alone or complicated a pre-existing renal lesion.

Having referred to previous publications by his group at Hammersmith relating to the disturbed physiology in acute tubular necrosis[1] and to the conservative management of such cases by careful water and electrolyte balance and protein-free, high-calorie diet,[2] Dr. Bull took up some special points in treatment. Anæmia was common in acute tubular necrosis, and the hæmoglobin concentration should be kept above 70% of normal by transfusion of packed red cells. Where feeding by intragastric drip was difficult because of vomiting, he advocated the passing of a 'Polythene' catheter into the superior vena cava and the infusion of 40% glucose solution containing 2500 units of heparin per litre. Such treatment could be maintained for at least two weeks. Dangerous hyperpotassæmia was not common in the well-managed cases, except where severe infection caused excessive tissue breakdown or where potassium was administered in therapeutic error. The routine use of potassium citrate for patients in urological wards was to be guarded against. Some centres considered a high serum-potassium level an absolute indication for some form of dialysis, but such treatment was too dangerous and complicated for routine use. As an emergency treatment glucose and insulin could be injected intravenously. This could be followed, if need be, by feeding cation-exchange resin in the sodium cycle—a measure which he had found more effective than intermittent peritoneal dialysis. In the early diuretic phase potassium

2. Bull, G. M., Joekes, A. M., Lowe, K. G. *Lancet*, 1949, ii, 229.

deficiency could readily occur and was best prevented by allowing a liberal intake of potassium (e.g., as fruit) about two days after diuresis had been frankly established. Infection was an important cause of death in anuria and hence penicillin should be given routinely. One dose was sufficient whilst the patient was anuric and unable to excrete the antibiotic. Similarly with the other antibiotics there was no need for continued dosage during anuria, and with some of them there was the risk of toxic effects. For example, an anuric patient could get 2 g. of aureomycin initially and then about 1 g. in divided doses until diuresis occurred.

Mr. Ashton Miller discussed surgical measures in the broad group of anurias. Renal decapsulation was unjustifiable as, in his experience, the capsule of the kidney was rarely tense in these conditions and the operation was only occasionally followed by diuresis. Such diuresis, from the natural history of the disease, was to be expected coincidentally in some cases. Renal decapsulation did not, by the way, lead to renal sympathectomy. He also advised against the use of renal sympathetic block in the established anurias. Turning to the obstructive anurias, Mr. Miller stated that ligation of a ureter led to short-lived loin pain and a non-functioning kidney that was capable of functioning again if the obstruction were relieved within fourteen days. The term "calculous anuria" should not be used for the terminal stages of bilateral calculous disease but for cases where both ureters or the ureter of a sole functioning kidney were obstructed. Obstruction was commonest in the upper third of the ureter and normally led to colic and a palpable tender kidney. Obstruction was rarely absolutely complete. Usually there was X-ray evidence of the site of obstruction. In puzzling cases old surgical practices of operating on the side where pain was last felt or where muscular rigidity persisted should not be forgotten.

In anuria it was always imperative to determine whether obstruction was present, and this usually involved ureteric catheterisation. Normally a rapid return of renal function occurred after the obstruction was released. When a calculus had been pushed back into the renal pelvis, operation should be deferred until the general condition had improved following diuresis. Where a calculus could not be dislodged and the catheter by-passed it, thus allowing drainage, then the catheter should be removed after twenty-four hours and open operation performed. "Reflex anuria" was a blunderbuss term that he did not favour, especially in the absence of any experimental evidence of renorenal shunt. It had been used loosely, for example, where a stone blocked one ureter and function had failed in the other kidney on account of severe dehydration or other circulatory disturbance. Sulphonamide obstructive anurias were still common, especially in febrile dehydrated patients. Sulphonamide crystals were rarely found, and more commonly there was only a brown deposit of epithelial cells and red blood-cells. In one patient removal of such debris was followed by diuresis, but the urine-flow fell off again and the secondary episode of anuria had all the characteristics of acute tubular necrosis. Recovery eventually followed with the use of the Hammersmith régime. He felt that there was no sharp division between sulphonamide obstructive anuria and sulphonamide tubular necrosis. Acute pyelonephritis occasionally led to ureteric obstruction from inflammatory products lodging in the lower end of the ureter even in the absence of treatment with sulphonamides. Obstruction from external pressure on the ureter might occur, for example, after gynæcological operations and was usually only seen by the urologist after a lapse of more than forty-eight hours. At this time pyelostomy was indicated as an emergency measure; later on, the lower end of the ureter could be exposed, and divided and reimplanted into the bladder. In pelvic carcinomas sudden anuria might occur, an drainage of the ureters seemed indicated only whe treatment of the carcinoma was possible.

In the discussion that followed, Mr. John Sophia assembled the recent information that seemed to favou the operation of the Oxford shunt in the ætiology o some anurias and made a plea for surgical intervention t reverse this postulated mechanism. Dr. R. H. Paramor felt that spinal anæsthesia still merited consideratio in the treatment of the anurias. Mr. A. W. Badenoch referred to the possibility of renal function returnin after an obstructive episode lasting longer than tw weeks; and the President referred to obstruction du to tuberculous stricture of the ureter.

In summing up, Dr. Bull referred to 36 cases, collected between the three opening speakers, in which anuria due to acute tubular necrosis had not been influenced by renal sympathetic block.

SOCIETY FOR ENDOCRINOLOGY

Posterior Pituitary Gland

The 34th meeting of the Society for Endocrinology, held in Cambridge on June 20, was devoted to a symposium on the Posterior Pituitary Gland. Dr. G. W. Harris was in the chair.

LOCALISATION OF OSMORECEPTORS

Mr. P. A. Jewell and Prof. E. B. Verney, F.R.S., said that intracarotid injection of hypertonic sodium chloride solution has been found to inhibit water diuresis by causing release of the antidiuretic hormone from the posterior pituitary. Investigation of the vascular bed of the internal carotid artery showed that this vessel supplies the pituitary gland and the anterior hypothalamus, including the greater part of the supraoptic nucleus and paraventricular nucleus, as well as other parts of the prosencephalon. Proof was given that the receptive elements, the osmoreceptors, stimulated by the administration of hypertonic saline do not lie in the pars nervosa of the pituitary. The findings in an animal in which one internal carotid artery was tied intradurally suggest that the receptors lie in the prosencephalon.

RELEASE OF ANTIDIURETIC HORMONE

Dr. Mary Pickford described the release of antidiuretic hormone from the posterior pituitary following injections of acetylcholine, nicotine, morphine, and ferritin. Acetylcholine is rendered temporarily ineffective in this respect after application of di-isopropylfluorophosphonate (D.F.P.) to the supraoptic nuclei. Intracarotid injection of adrenaline before an antidiuretic dose of acetylcholine regularly annuls the action of the latter. Morphine is still effective in inhibiting a high rate of urine flow if applied directly to the supraoptic nerve-cells, whether or not the cholinesterase of the cells has been disorganised by D.F.P. It appears that the cells of the supraoptic nuclei, like others in the body, can be activated by different types of stimuli, some arriving by nervous pathways, some being directly chemical, and some being physical or physicochemical. Also like the cells of other tissues, when the supraoptic nerve-cells are rendered unresponsive to one type of stimulus they can still respond to another.

EXTRACTS OF NEURAL LOBE

Prof. H. B. van Dyke (New York) described work in which he and his colleagues[1] extracted a protein from the pars nervosa of the pituitary with the biological activities of both principles (antidiuretic pressor and oxytocic) in about the same ratio as they are found in the gland. Its molecular weight was about 30,000, and its biological activity was found to be low (1 unit = 61 μg.). Although considerable evidence has been obtained that oxytocic and antidiuretic activities are present in constant ratios and that the protein is homogeneous, the possibility of adsorption of highly active principles on to an inert protein molecule has not been excluded. The highly purified principles recently isolated by du Vigneaud and his co-workers[2] were discussed. These principles have been isolated in extremely active forms—1 unit of the oxytocic principle being contained in 1·25 μg., and 1 unit of the antidiuretic-vasopressor principle in 1·6 μg. The amino-acid content of these two principles has been investigated; tyrosine, cystine, aspartic acid, glutamic acid, glycine, and proline are common to both, whereas arginine and phenylalanine characterise the oxytocic principle and leucine and isoleucine characterise the antidiuretic-vasopressor principle. Using these principles, various workers have established that neither the contraction of the isolated rat uterus nor the ejection of milk by the lactating mammary gland is a specific test for the oxytocic principle, whereas the depressor response of the fowl's blood-pressure appears to meet this requirement provided that contamination by antidiuretic-vasopressor principle is not excessive. The extremely sensitive antidiuretic test in the dog proved specific for the antidiuretic-vasopressor principle. It is not yet possible to decide whether the neurohypophysis secretes a large molecule containing both oxytocic and antidiuretic-vasopressor principles, or smaller molecules of highly active principles. The separate secretion of the latter has more teleological attraction.

---

[1] van Dyke, H. B., Chow, B. F., Greep, R. O., Rothen, A. *J. Pharmacol.* 1942, 74, 190.

FATE OF POSTERIOR PITUITARY PRINCIPLES

Prof. H. S. Heller discussed the rapid inactivation of antidiuretic extracts by defibrinated blood, serum, and liver homogenate. When injected intravenously the antidiuretic activity of posterior pituitary extracts was found to disappear rapidly from the circulating blood. An antidiuretic substance appeared in the urine of animals after intravenous injection of large doses of such extracts. Recent unpublished experiments by Ginsburg and Heller have shown that the liver and kidney both play a part in the "clearance" of the antidiuretic principle: it would seem that in addition to excreting it, the kidney also removes it by another, as yet unknown, process.

MILK EJECTION

Mr. B. A. Cross described the evidence underlying the present concept of a milk-ejection reflex.[3] The act of suckling stimulates a nervous reflex excitation of the posterior pituitary gland, and the secretion from this gland causes contraction of some element in the mammary gland and thus a positive ejection of milk from the mother to the young. Recent work, using du Vigneaud's highly active oxytocic and antidiuretic extracts, indicates that the posterior pituitary principle underlying milk ejection is the oxytocic principle, and not a mixture of the two as had been previously suggested. Mr. Cross also discussed unpublished work in which it was found that previous administration of adrenaline, or stimulation of the posterior region of the hypothalamus with resultant sympathetic excitation, will inhibit the milk-ejection reflex. Since the same procedures inhibit the milk-ejection effect of posterior pituitary extract it is likely that the effect of adrenaline is, at least in part, on the mammary gland itself.

SECRETION OF ANTIDIURETIC HORMONE

Dr. A. G. Lewis produced evidence that after 18 hours' dehydration a normal person had posterior pituitary hormone in the circulation with an antidiuretic activity equal to approximately 20 milli-units 'Pitressin.' It seems unlikely that the 5 milli-units per ml. of antidiuretic substance which has been detected by rat assay of human serum has any physiological action. Direct assay in man has shown that human serum contains less than 0·1 milli-unit per ml. after 12 hours' dehydration. Emotional stimuli, intravenous infusion of acetylcholine, hypertonic saline, nicotine, or morphine, anæsthesia and surgical operations, and syncope may all produce large releases of the antidiuretic hormone in man.

DIABETES INSIPIDUS

Dr. J. E. Gates described the results of investigation, in collaboration with Dr. O. Garrod, on fifteen patients with diabetes insipidus. Pitressin tests separate the rare pitressin-resistant cases. Water deprivation gives variable results. Hickey and Hare's test with hypertonic saline may be nullified by an osmotic diuresis. Nicotine intravenously causes little or no antidiuresis when given in doses large enough to cause antidiuresis in normal persons; larger doses usually cause some antidiuresis. The effect of nicotine in clinical diabetes insipidus supports the belief that nicotine stimulates the secretion of the antidiuretic hormone. The response to large doses suggests that the lesion of the supraopticohypophysial system is often not complete.

Reviews of Books

Psychiatry in General Practice

C. A. H. Watts, M.D. Durh.; B. M. Watts, M.B. Durh. London: J. & A. Churchill. 1952. Pp. 228. 12*s.* 6*d.*

Dr. and Mrs. Watts have written an original and stimulating book showing, with many illustrative cases, how the generally accepted principles and techniques of psychiatry have been applied to the problems of a busy general practice in a mining district of Leicestershire. Dr. C. A. H. Watts appears to have had the advantage of learning and practising psychiatric methods in the war-time school of the South African Medical Corps, perhaps thus escaping the formidable task of devising them ab initio in the surroundings of an established practice; but this book shows clearly that, with a sufficiency of knowledge and the will and patience to use it, a general practitioner can make of psychiatry the kind of specialty another may make of obstetrics or pædiatrics.

The authors divide psychotherapy into three grades. Major psychotherapy, like major surgery, is for the specialist; elementary first-aid psychotherapy is an inescapable part of every doctor's task; while the intermediate field should belong to the general practitioner but too often goes uncultivated from real or supposed lack of time, from lack of knowledge or imagination, or from plain dislike. The book explores this intermediate field, section by section, showing the problems which commonly present themselves, the guise in which they appear, and how their solution may be attempted. The unsuccessful or half-successful case is not omitted, and the limitations of psychotherapy are clearly indicated; the authors do not for a moment pretend that it can relieve a practice of every troublesome psychopath or neuropath, but they do maintain that to tackle emotional problems on their own ground and not merely to treat their physical symptoms will in the end save time, and will restore many patients, if not to full health, at least to working capacity. Preventive psychotherapy, especially in childhood and before marriage, is fully considered; and there are interesting reflections on mental hospitals and on the limited usefulness of voluntary admission. The book ends with a reasoned plea for mental wings in general hospitals—for the diagnosis and treatment, as distinct from the segregation and maintenance, of the mentally sick—and for a multiplication of general-practitioner psychiatrists.

Practitioners will find much here to stimulate and help them, and teachers could deduce from these pages what kind of psychiatric instruction the future practitioner needs and ought to have.

deficiency could readily occur and was best prevented by allowing a liberal intake of potassium (e.g., as fruit) about two days after diuresis had been frankly established. Infection was an important cause of death in anuria and hence penicillin should be given routinely. One dose was sufficient whilst the patient was anuric and unable to excrete the antibiotic. Similarly with the other antibiotics there was no need for continued dosage during anuria, and with some of them there was the risk of toxic effects. For example, an anuric patient could get 2 g. of aureomycin initially and then about 1 g. in divided doses until diuresis occurred.

Mr. ASHTON MILLER discussed surgical measures in the broad group of anurias. Renal decapsulation was unjustifiable as, in his experience, the capsule of the kidney was rarely tense in these conditions and the operation was only occasionally followed by diuresis. Such diuresis, from the natural history of the disease, was to be expected coincidentally in some cases. Renal decapsulation did not, by the way, lead to renal sympathectomy. He also advised against the use of renal sympathetic block in the established anurias. Turning to the obstructive anurias, Mr. Miller stated that ligation of a ureter led to short-lived loin pain and a non-functioning kidney that was capable of functioning again if the obstruction were relieved within fourteen days. The term "calculous anuria" should not be used for the terminal stages of bilateral calculous disease but for cases where both ureters or the ureter of a sole functioning kidney were obstructed. Obstruction was commonest in the upper third of the ureter and normally led to colic and a palpable tender kidney. Obstruction was rarely absolutely complete. Usually there was X-ray evidence of the site of obstruction. In puzzling cases old surgical practices of operating on the side where pain was last felt or where muscular rigidity persisted should not be forgotten.

In anuria it was always imperative to determine whether obstruction was present, and this usually involved ureteric catheterisation. Normally a rapid return of renal function occurred after the obstruction was released. When a calculus had been pushed back into the renal pelvis, operation should be deferred until the general condition had improved following diuresis. Where a calculus could not be dislodged and the catheter by-passed it, thus allowing drainage, then the catheter should be removed after twenty-four hours and open operation performed. "Reflex anuria" was a blunderbuss term that he did not favour, especially in the absence of any experimental evidence of renorenal shunt. It had been used loosely, for example, where a stone blocked one ureter and function had failed in the other kidney on account of severe dehydration or other circulatory disturbance. Sulphonamide obstructive anurias were still common, especially in febrile dehydrated patients. Sulphonamide crystals were rarely found, and more commonly there was only a brown deposit of epithelial cells and red blood-cells. In one patient removal of such debris was followed by diuresis, but the urine-flow fell off again and the secondary episode of anuria had all the characteristics of acute tubular necrosis. Recovery eventually followed with the use of the Hammersmith régime. He felt that there was no sharp division between sulphonamide obstructive anuria and sulphonamide tubular necrosis. Acute pyelonephritis occasionally led to ureteric obstruction from inflammatory products lodging in the lower end of the ureter even in the absence of treatment with sulphonamides. Obstruction from external pressure on the ureter might occur, for example, after gynæcological operations and was usually only seen by the urologist after a lapse of more than forty-eight hours. At this time pyelostomy was indicated as an emergency measure; later on, the lower end of the ureter could be exposed, and divided and reimplanted into the bladder. In pelvic carcinomas sudden anuria might occur, and drainage of the ureters seemed indicated only when treatment of the carcinoma was possible.

In the discussion that followed, Mr. JOHN SOPHIAN assembled the recent information that seemed to favour the operation of the Oxford shunt in the ætiology of some anurias and made a plea for surgical intervention to reverse this postulated mechanism. Dr. R. H. PARAMORE felt that spinal anæsthesia still merited consideration in the treatment of the anurias. Mr. A. W. BADENOCH referred to the possibility of renal function returning after an obstructive episode lasting longer than two weeks; and the PRESIDENT referred to obstruction due to tuberculous stricture of the ureter.

In summing up, Dr. BULL referred to 36 cases, collected between the three opening speakers, in which anuria due to acute tubular necrosis had not been influenced by renal sympathetic block.

SOCIETY FOR ENDOCRINOLOGY

Posterior Pituitary Gland

THE 34th meeting of the Society for Endocrinology, held in Cambridge on June 20, was devoted to a symposium on the Posterior Pituitary Gland. Dr. G. W. HARRIS was in the chair.

LOCALISATION OF OSMORECEPTORS

Mr. P. A. JEWELL and Prof. E. B. VERNEY, F.R.S., said that intracarotid injection of hypertonic sodium chloride solution has been found to inhibit water diuresis by causing release of the antidiuretic hormone from the posterior pituitary. Investigation of the vascular bed of the internal carotid artery showed that this vessel supplies the pituitary gland and the anterior hypothalamus, including the greater part of the supraoptic nucleus and paraventricular nucleus, as well as other parts of the prosencephalon. Proof was given that the receptive elements, the osmoreceptors, stimulated by the administration of hypertonic saline do not lie in the pars nervosa of the pituitary. The findings in an animal in which one internal carotid artery was tied intradurally suggest that the receptors lie in the prosencephalon.

RELEASE OF ANTIDIURETIC HORMONE

Dr. MARY PICKFORD described the release of antidiuretic hormone from the posterior pituitary following injections of acetylcholine, nicotine, morphine, and ferritin. Acetylcholine is rendered temporarily ineffective in this respect after application of di-isopropylfluorophosphonate (D.F.P.) to the supraoptic nuclei. Intracarotid injection of adrenaline before an antidiuretic dose of acetylcholine regularly annuls the action of the latter. Morphine is still effective in inhibiting a high rate of urine flow if applied directly to the supraoptic nerve-cells, whether or not the cholinesterase of the cells has been disorganised by D.F.P. It appears that the cells of the supraoptic nuclei, like others in the body, can be activated by different types of stimuli, some arriving by nervous pathways, some being directly chemical, and some being physical or physicochemical. Also like the cells of other tissues, when the supraoptic nerve-cells are rendered unresponsive to one type of stimulus they can still respond to another.

EXTRACTS OF NEURAL LOBE

Prof. H. B. VAN DYKE (New York) described work in which he and his colleagues[1] extracted a protein from the pars nervosa of the pituitary with the biological activities of both principles (antidiuretic pressor and oxytocic) in about the same ratio as they are found in the gland. Its molecular weight was about 30,000, and its biological activity was found to be low (1 unit = 61 μg.). Although considerable evidence has been obtained that oxytocic and antidiuretic activities are present in constant ratios and that the protein is homogeneous, the possibility of adsorption of highly active principles on to an inert protein molecule has not been excluded. The highly purified principles recently isolated by du Vigneaud and his co-workers[2] were discussed. These principles have been isolated in extremely active forms—1 unit of the oxytocic principle being contained in 1·25 μg., and 1 unit of the antidiuretic-vasopressor principle in 1·6 μg. The amino-acid content of these two principles has been investigated; tyrosine, cystine, aspartic acid, glutamic acid, glycine, and proline are common to both, whereas arginine and phenylalanine characterise the oxytocic principle and leucine and isoleucine characterise the antidiuretic-vasopressor principle. Using these principles, various workers have established that neither the contraction of the isolated rat uterus nor the ejection of milk by the lactating mammary gland is a specific test for the oxytocic principle, whereas the depressor response of the fowl's blood-pressure appears to meet this requirement provided that contamination by antidiuretic-vasopressor principle is not excessive. The extremely sensitive antidiuretic test in the dog proved specific for the antidiuretic-vasopressor principle. It is not yet possible to decide whether the neurohypophysis secretes a large molecule containing both oxytocic and antidiuretic-vasopressor principles, or smaller molecules of highly active principles. The separate secretion of the latter has more teleological attraction.

---

[1] van Dyke, H. B., Chow, B. F., Greep, R. O., Rothen, A. J. Pharmacol. 1942, 74, 190.

FATE OF POSTERIOR PITUITARY PRINCIPLES

Prof. H. S. **Heller** discussed the rapid inactivation of antidiuretic extracts by defibrinated blood, serum, and liver homogenate. When injected intravenously the antidiuretic activity of posterior pituitary extracts was found to disappear rapidly from the circulating blood. An antidiuretic substance appeared in the urine of animals after intravenous injection of large doses of such extracts. Recent unpublished experiments by Ginsburg and Heller have shown that the liver and kidney both play a part in the "clearance" of the antidiuretic principle: it would seem that in addition to excreting it, the kidney also removes it by another, as yet unknown, process.

MILK EJECTION

Mr. B. A. **Cross** described the evidence underlying the present concept of a milk-ejection reflex.[3] The act of suckling stimulates a nervous reflex excitation of the posterior pituitary gland, and the secretion from this gland causes contraction of some element in the mammary gland and thus a positive ejection of milk from the mother to the young. Recent work, using du Vigneaud's highly active oxytocic and antidiuretic extracts, indicates that the posterior pituitary principle underlying milk ejection is the oxytocic principle, and not a mixture of the two as had been previously suggested. Mr. Cross also discussed unpublished work in which it was found that previous administration of adrenaline, or stimulation of the posterior region of the hypothalamus with resultant sympathetic excitation, will inhibit the milk-ejection reflex. Since the same procedures inhibit the milk-ejection effect of posterior pituitary extract it is likely that the effect of adrenaline is, at least in part, on the mammary gland itself.

SECRETION OF ANTIDIURETIC HORMONE

Dr. A. G. **Lewis** produced evidence that after 18 hours' dehydration a normal person had posterior pituitary hormone in the circulation with an antidiuretic activity equal to approximately 20 milli-units 'Pitressin.' It seems unlikely that the 5 milli-units per ml. of antidiuretic substance which has been detected by rat assay of human serum has any physiological action. Direct assay in man has shown that human serum contains less than 0·1 milli-unit per ml. after 12 hours' dehydration. Emotional stimuli, intravenous infusion of acetylcholine, hypertonic saline, nicotine, or morphine, anæsthesia and surgical operations, and syncope may all produce large releases of the antidiuretic hormone in man.

DIABETES INSIPIDUS

Dr. J. E. **Cates** described the results of investigation, in collaboration with Dr. O. Garrod, on fifteen patients with diabetes insipidus. Pitressin tests separate the rare pitressin-resistant cases. Water deprivation gives variable results. Hickey and Hare's test with hypertonic saline may be nullified by an osmotic diuresis. Nicotine intravenously causes little or no antidiuresis when given in doses large enough to cause antidiuresis in normal persons; larger doses usually cause some antidiuresis. The effect of nicotine in clinical diabetes insipidus supports the belief that nicotine stimulates the secretion of the antidiuretic hormone. The response to large doses suggests that the lesion of the supraopticohypophysial system is often not complete.

Reviews of Books

Psychiatry in General Practice

C. A. H. Watts, M.D. Durh.; B. M. Watts, M.B. Durh.
London: J. & A. Churchill. 1952. Pp. 228. 12*s.* 6*d.*

Dr. and Mrs. Watts have written an original and stimulating book showing, with many illustrative cases, how the generally accepted principles and techniques of psychiatry have been applied to the problems of a busy general practice in a mining district of Leicestershire. Dr. C. A. H. Watts appears to have had the advantage of learning and practising psychiatric methods in the war-time school of the South African Medical Corps, perhaps thus escaping the formidable task of devising them ab initio in the surroundings of an established practice; but this book shows clearly that, with a sufficiency of knowledge and the will and patience to use it, a general practitioner can make of psychiatry the kind of specialty another may make of obstetrics or pædiatrics.

The authors divide psychotherapy into three grades. Major psychotherapy, like major surgery, is for the specialist; elementary first-aid psychotherapy is an inescapable part of every doctor's task; while the intermediate field should belong to the general practitioner but too often goes uncultivated from real or supposed lack of time, from lack of knowledge or imagination, or from plain dislike. The book explores this intermediate field, section by section, showing the problems which commonly present themselves, the guise in which they appear, and how their solution may be attempted. The unsuccessful or half-successful case is not omitted, and the limitations of psychotherapy are clearly indicated; the authors do not for a moment pretend that it can relieve a practice of every troublesome psychopath or neuropath, but they do maintain that to tackle emotional problems on their own ground and not merely to treat their physical symptoms will in the end save time, and will restore many patients, if not to full health, at least to working capacity. Preventive psychotherapy, especially in childhood and before marriage, is fully considered; and there are interesting reflections on mental hospitals and on the limited usefulness of voluntary admission. The book ends with a reasoned plea for mental wings in general hospitals—for the diagnosis and treatment, as distinct from the segregation and maintenance, of the mentally sick—and for a multiplication of general-practitioner psychiatrists.

Practitioners will find much here to stimulate and help them, and teachers could deduce from these pages what kind of psychiatric instruction the future practitioner needs and ought to have.

Renal Function

Transactions of the Second Conference. Editor: STANLEY E. BRADLEY, department of medicine, College of Physicians and Surgeons, Columbia University. New York: Josiah Macy, Jr., Foundation. 1951. Pp. 178. $3.00.

GONE are the days when a conference on renal function discusses, in simple language, such topics as glomerular filtration or tubular reabsorption, or even devotes its time to a review of clearance techniques. Investigation of renal activity during the past years has shown how intimately the endocrine glands are concerned in its control, and in this record of the second Josiah Macy conference, held in October, 1950, we find discussions on antidiuretic factors, on the influence of the adrenal cortex on water metabolism, on sodium excretion, and on the action of A.C.T.H. and cortisone on renal function in man. Much that is reported has been already published, much is new and as yet unproven, part is still hypothesis. A review of active work is of course the purpose of such conferences and it is valuable to have the discussion, as well as the main papers, recorded.

Das Phäochromozytom

Professor H. SACK, Chefarzt der inneren Klinik, Städtischen Krankenanstalten, Krefeld. Stuttgart: Thieme. 1951. Pp. 93. D.M. 11.70.

THIS is a short but thorough account of our present knowledge of the adrenaline and noradrenaline secreting tumours of the adrenal cortex. Professor Sack has drawn both on his own experience and on the growing literature of the subject. Starting with a historical survey, he discusses the clinical features, the physiopathology, and the various pharmacological methods used in the diagnosis of this rare but important tumour. He has given us a valuable and timely review, supplemented by a full bibliography.

Photography of Patients

H. LOU GIBSON, F.B.P.A., A.P.S.A., medical division, Eastman Kodak Company, Rochester, New York. Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 118. 40*s.*

CLINICIANS who are amateur photographers will find parts of this book of great assistance in making records of their patients. The emphasis is on the practical, and there is a good section on methods of adapting standard small cameras for carrying out close-up work quickly and easily. The illustrations are good and well reproduced, but two of the prints have been transposed on p. 102. Most of the materials mentioned in the table are not to be had in this country, but in many cases it would not be difficult to adapt our own materials. It is a pity that so much of this monograph has been taken up with the basic principles of photography; this information is more cheaply available in a dozen standard textbooks.

Educability of Cerebral Palsied Children

M. I. DUNSDON, M.A., F.B.PS.S. Publication no. 4 of the National Foundation for Educational Research in England and Wales. London: Newnes Educational Publishing Company. 1952. Pp. 163. £1 1*s.*

IN this book are reported the results of a three-year investigation into the educability of children with cerebral palsy. The difficulty of assessing intelligence in a severely handicapped child is discussed, and the problems presented to the teacher by physical handicaps (including defects of special sense and speech difficulties) and by deficiencies in intelligence, temperament, and social adjustment are considered. Data on the frequency and extent of the various handicaps, and correlation of these with competence as assessed in various ways, are given in tabular form. No statistical analysis is attempted, and the conclusions drawn are sometimes of doubtful validity.

The incidence of cerebral palsy in England and Wales is calculated from replies by 101 local education authorities to a questionary sent out by the British Council for the Welfare of Spastics, but most of the other information presented is based on individual assessments of "abilities, aptitudes and attainments" made in most instances by the author. The majority of cases had been referred for admission to a special cerebral-palsy school. Such cases are often referred because they present special problems, and hence, as pointed out by the author, they do not constitute a fair sample for the calculation of general incidences. The proportions of these cases included in the tables is not always stated.

In making a direct attack on the question of educability—an inquiry into the educational progress actually achieved by cerebral palsied children—the author was unfortunate. "Rapid turnover of children for various reasons, frequent staff changes, necessary changes in routines due to general re-organisation, and interruptions due to illness among children or staff, all militated against the carrying out of planned experiments." Few will doubt that some of these factors must have influenced the rate of educational progress achieved, and there is some evidence in the text that this rate was lower than the best possible. Yet the author accepts the results as of general application; her plan for the educational care of cerebral palsied children in England and Wales is based largely on them.

It may be said that in this book the difficulties to be encountered by any teacher who has to deal with cerebral palsy are well set out, but that little contribution is made to overcoming them.

Use of Tracer Elements in Biology (London: Heinemann. 1951. Pp. 57. 3*s.* 6*d.*).—This little book by Mr. W. G. Overend, PH.D., of Birmingham, begins by explaining very briefly how radioactive isotopes of usually stable elements are formed. The use of suitable radioactive (and sometimes of stable) isotopes of carbon, nitrogen, hydrogen, oxygen, sulphur, and phosphorus in biology is described and illustrated at some length and mention is made of some others like iron and iodine. There is a very short account of the use of tracers in medicine. The language is clear and only absolutely essential technical formulæ are used. The book can be confidently recommended to those who want to grasp, in outline, the facts behind the use of tracers and who are defeated by the larger volumes.

British Encyclopædia of Medical Practice (2nd ed. London: Butterworth Medical Publications. 1952. Vol. 10. Pp. 678. £3 5*s.*). *Cumulative Supplement*, 1952 (Pp. 126. £1 5*s.*). *Medical Progress*, 1952 (Pp. 319. £1 12*s.* 6*d.*).—The editor-in-chief, Lord Horder, and his contributors are within sight of the finishing line. They run on as strongly as ever in the 10th stage of their marathon which takes them from pituitary-gland diseases (by Dr. H. Gardiner-Hill) to retina diseases (by Mr. R. C. Davenport). They have set a cracking pace all along; it is barely 20 months since we reviewed the first volume of the 2nd edition, and now a final spurt will carry them across the line before this Olympic year is out. The *Cumulative Supplement* contains material that has been substantiated since the publication of the main volumes, and *Medical Progress* covers by critical survey and abstract the advances of the last year or so.

Textbook of Surgical Treatment (4th ed. Edinburgh: E. & S. Livingstone. 1952. Pp. 744. 45*s.*).—Under Prof. C. F. W. Illingworth's editorship this book maintains its popularity north of the Tweed, and its 22 contributors well reflect Scottish surgical practice. The new edition has been extensively revised and new sections on congenital heart conditions and hypertensive states have been added. In general the senior student will find what he wants, but a few minor criticisms may be made. Sulphanilamide, instead of its less toxic derivatives, is used for septic conditions and is recommended for local use, though experience has shown how ineffective it is in wounds. The newer antibiotics streptomycin, aureomycin, and chloramphenicol are not mentioned. Some surgeons would dispute the omission of urethrotomy as a treatment for stricture. No account is given of complete cystectomy, on the ground that it is too advanced for this book; yet the complex procedures required to remedy the tetrad of Fallot are fully described and well illustrated. In the instructions for removing the rectum by the abdomino-perineal method no warning of the proximity of the left ureter is given. Resection of the rectum with restoration of continuity of the bowel finds no place. From the account of amputation of the rectum for prolapse it would be fair to deduce that this was a successful solution of the difficulty, which it is not. Yet who could compile a book covering so great an area of knowledge without leaving some points open to criticism? Professor Illingworth, in fact, has left surprisingly few.

THE LANCET

LONDON: SATURDAY, JULY 5, 1952

Complications of Controlled Hypotension

In many eyes the practice of deliberately inducing hypotension to lessen bleeding during operations has become a mark of modernity and progress. Hitherto, reports have mostly been enthusiastic, though last year we suggested that caution was needed.[1] Our impression now is that hypotension is often induced for insufficient reasons, with too little regard for the patients' physical state, and even with little check on the blood-pressure during operation. Tooth extractions and the smaller orthopædic operations are taken by some to be suitable for hypotension, as are laryngectomy in feeble carcinomatous patients and prostatectomy in the semi-uræmic. The result is that at meetings of anæsthetists round the country instances are recounted, by word of mouth, of death and near-death. Of the known deaths, some have taken place on the table, others after a few hours without recovery from the anæsthetic, and still others somewhat inexplicably after two or three days. So widespread is the feeling that controlled hypotension is less safe than some surgeons and anæsthetists believe, that the Section of Anesthesiology of the Yale University School of Medicine has circularised British anæsthetists asking for anonymous reports of accidents with the method. As the circular puts it:

> "Certain fatal and non-fatal complications resulting from the use of the technique have been much more common than was previously supposed, but very little has been published concerning these disasters due to the very normal fear on the part of the involved surgeons and anesthetists of the possibility of the institution of medico-legal action."

Evidence which may explain some of the disasters is now coming to light. **McQueen**[2] studied the glomerular filtration-rate, renal plasma-flow, and urine-flow in volunteers who received 100 mg. of hexamethonium in the proper posture, and he found a sharp fall in the filtration-rate and in the urine-flow. He points out that since hexamethonium is excreted by the kidneys, a gross fall of blood-pressure is likely to delay its excretion and prolong its action. In our present issue Dr. **Mackinnon** records similar findings: he has found that pentamethonium reduces both the glomerular filtration-rate and the effective renal blood-flow. As might be expected, hypotension has a disagreeable effect on the liver. Dr. **Bromage**, whose paper we also publish this week, describes macroscopic observations on the liver in 17 patients with hypotension during anæsthesia, and says that in 14 there were changes clearly indicating hypoxia. When the systolic pressure was between 45 and 60 mm. Hg the liver appeared cyanosed and was turgid and rubbery; but it quickly became pink and of normal consistence when the pressure was raised with 'Methedrine.' Dr. **Bromage** emphasises that these changes take place before much else seems wrong with the patient; and thus occult liver damage may be more likely than general inspection indicates.

These reports are probably the first of many in similar strain. They underline the need for carefully selecting cases in which the blood-pressure is to be deliberately lowered: without good reason none but the robust should be subjected to this procedure. Where hypotension is proposed, the surgeon must ask himself whether the lessening of capillary oozing during the operation is so important that it really compensates for the possibility of grave interference with some vital body process. Anæsthetists, too, will clearly see the need for moderation in the use of controlled hypotension, and for careful supervision during and after the operation. Some of those most favourable to the method will nevertheless agree with Dr. **Bromage** that the blood-pressure should never be allowed to fall below 60 mm. Hg.

Clot Retraction

The 18th-century doctors who used bleeding in everyday therapy naturally observed the clotting of blood and remarked on the fact that the clot retracted and expressed serum. **Charles Thackrah** of Leeds, is best known for having given the first systematic account of industrial medicine in his book *The effects of arts, trades and professions and of civic states and habits of living, on health and longevity, with suggestions for the removal of many of the agents which produce disease and shorten the duration of life.* But he also wrote a book on blood, in which he noted that the average proportion of serum squeezed out from normal clots was 42%. This early estimate was accurate, and **Thackrah** also remarked that temperature variations influenced the result. Since then there have been many attempts to measure clot retraction, and almost as many explanations of its mechanism—a multiplicity partly due to the singular reluctance of workers in this small corner of hæmatology to consult previous reports. Perhaps this is because the problem has specially interested the "gadgeteer"—an individualistic type. Now, however, Dr. O. E. **Budtz-Olsen**[1] has put us in his debt by collecting and collating the known information, providing a good method of estimation, and propounding a reasonable explanation.

The retraction of the clot of blood formed after shedding is measured by the ratio between the volume of the serum expressed and the original volume of the blood; this ratio is usually given as a percentage. The retraction is influenced by many factors, including temperature, gravity, the size, shape, and surface of the vessel used to collect the blood, and even the material the container is made of. **Budtz-Olsen** avoids most of these difficulties by suspending the blood in a mixture of liquid paraffin and trichlorethylene adjusted to the specific gravity of the blood. A known volume of blood withdrawn from a vein is ejected into some of this fluid contained in a tall vessel; the blood forms a globule which remains stationary, suspended in the liquid. When it clots and the clot begins to retract and squeeze out serum, the serum rises to the surface and the remaining clot and enmeshed red cells fall downwards; the serum can be pipetted off and measured.

---

[1] Budtz-Olsen, O. E. Clot Retraction. Oxford: Blackwell Scientific Publications. 1951. Pp. 149. 25s.

By this method Budtz-Olsen studied once again the influence of various factors, such as temperature, and the presence of red and white blood-cells in the expressed serum; and he found that the blood-platelets are the most important factor. When the other clotting factors of blood are normal, clot retraction depends directly on the number of platelets present. Fibrinogen is also important, and clots retract better when *less* fibrinogen is present. Consequently when blood is diluted, clot retraction, as is well known, remains more or less unaltered because the lowered platelet-count diminishes retraction and the lower fibrinogen content increases retraction, and these two effects tend to balance. The fibrin formed in the clot acts mechanically by holding serum in the clot and giving rise to a network that becomes denser, and therefore harder to pull together, the higher the fibrin concentration. Such an explanation assumes that fibrin plays only a passive part in clot retraction; Budtz-Olsen shows that this is so, and that the platelets are the active retractile agents.

When platelets are shed they are "activated" so that they will cause clot retraction; and experiments show that the activator is produced when prothrombin is converted to thrombin, though it is not thrombin itself. Activated platelets swell up and coalesce, and in the process they pull the fibrin network with them. The process is more easily followed in birds' blood, where the thrombocytes in shed blood can be seen to swell and throw out long processes which join with processes from other platelets; then these processes retract, drawing the two cells together until they fuse. Electron-microscope pictures of human blood have shown these processes very clearly.[2] Budtz-Olsen points out that in crabs, which have no fibrinogen in their blood, this so-called "viscous metamorphosis" of the amœbocytes or spindle-cells in the blood is the sole method of forming a network clot for hæmostasis, and the network of coalesced amœbocytes becomes firm by contraction. The lobster has some fibrinogen, but the amœbocyte clot forms first and the fibrin clot is added later. In birds there are specialised thrombocytes; while in mammals there are still more specialised platelets and the fibrin clot forms at the same time as the platelet changes occur, so the clot retracts steadily. Budtz-Olsen suggests that in mammals clot retraction is now a "phylogenetic relic"—a vestigial process that still remains although mammals (and birds) have now developed more efficient methods of hæmostasis. The blood-platelets of the mammal still undergo "viscous metamorphosis" and cause retraction of the fibrin clot; but they now have other functions—they release thromboplastin activator to initiate the clotting process, and they form masses that plug breaks in small vessels. If this hypothesis is correct, we should not expect to find that defective clot retraction causes ineffective hæmostasis. Clinical experience shows that this is so, unless the clot retraction is defective as in hæmorrhagic syndromes caused by low platelet-counts.

All this Dr. Budtz-Olsen presents, with full experimental details, in an astonishingly readable little monograph. The physician and the clinical pathologist can study it with detached appreciation; for, since clot retraction is a mere relic of our evolutionary history, there is no need to remember a list of conditions in which it should be estimated. The clinical pathologist has not to organise yet another test; nor need any research-worker fear that he will be asked if he has carried out "Budtz-Olsen's test for clot retraction." Nowadays investigations in hæmatology rarely have so happy a conclusion.

Recoverable Psychosis in the Old

Now that we are turning a considering eye on the ills of old people, many conditions which we have been accustomed to regard as terminal or irremediable are proving to be not so serious after all. Even mental disorders in old age, as Dr. Martin Roth and Dr. J. D. Morrissey[1] point out, do not really present the gloomy picture suggested by the rising rates of admission of these patients to mental hospitals. They quote the finding of R. E. L. Faris and H. W. Dunham, in 1939, that the number of admissions of the old to mental hospital varies with their degree of social security; and they think that the difference between the vast rise in admission-rates in the United States and the relatively smaller rise in Great Britain may well be due to differences in the social and economic status of the old in the two countries. They particularly emphasise that those admitted do not form a homogeneous group: some will deteriorate, certainly, and end their lives in senile dementia; but a large proportion will recover, and above all will respond to modern methods of treatment if these are used. This conclusion was reached from a study of 150 patients over sixty admitted to Graylingwell Hospital during 1948, and followed up until the end of March, 1951, either in hospital, or by letter, or by a visit from a psychiatric social worker. They judged that affective psychosis—usually depression—accounted for 81 (54%) of the cases, and senile psychosis for only 36 (24%). For the rest, 7 were diagnosed as cases of arteriosclerotic psychosis, 12 as schizophrenia, and 14 as confusion (quite apart from those cases in which confusional symptoms complicated some other disorder).

The follow-up studies showed that six months after admission 46 (more than half) of the 81 cases of affective psychosis were out of hospital, and only 5 had died. Of the 36 patients with senile psychosis only 5 had been discharged, and 19 had died. By the end of the study, some two to three years later, 43 of the affective patients had maintained their recovery, 7 had recovered and relapsed after discharge, 8 were ill in hospital, 19 (a quarter) had died, and 4 were untraced. Thus a substantial proportion were finding life worth living. Of the 36 with senile psychoses, 32 (nearly 90%) were dead, 3 were deteriorating inpatients, and 1 was untraced. These observations demonstrate the very real importance of distinguishing between the two types of psychosis, especially since patients with affective depression respond well to electroconvulsive therapy (E.C.T.). The conclusion that affective disorder and senile dementia are distinct is further supported by Roth and Morrisey's findings with a battery of tests on 84 patients over sixty admitted consecutively to Graylingwell.[2] The mean score of the affective patients was eight or nine times as good as that of the senile psychotics.

---

[2] See leading article, *Lancet*, 1950, i, 1076.

[1] *J. ment. Sci.* January, 1952, p. 66.

Among the features of depression at this time of life, apathy is common in long-standing cases. In the present series hypochondriacal and paranoid symptoms were more often found than in younger age-groups, and if prominent were an unfavourable sign. Neurotic symptoms, beginning for the first time, and suddenly, in old age often seemed to be a symptom of affective disorder and responded quickly to treatment. Of the 12 patients in the series who made a clear-cut attempt at suicide, all were cases of depression. Confusion, which sometimes leads to difficulty in the diagnosis during the acute phase, was present in only 3 cases of affective disorder, but was noted at the outset in 28 of the 36 patients with senile psychosis; and 18 of these were dead in six months. In the 12 cases of schizophrenia in this series the disorder had started after the patients had reached sixty; paraphrenic delusions were prominent, in a setting of well-preserved intellect and personality. The 7 cases of arteriosclerotic psychosis showed a fluctuating course with cerebrovascular symptoms, a patchy deterioration of personality, and relatively good insight.

The main task is to winnow out cases of affective disorder soon after admission, for failure to diagnose them may prove disastrous for the patients. "Depressive illness in the aged," as ROTH and MORRISSEY point out, "takes a terrible toll in death from exhaustion, pneumonia and other intercurrent infections"; and death after months or years in hospital, preceded by some physical decline and mental confusion, does not mean that the patient must have had a senile psychosis after all. It is easy to make mistakes at the start; for an apathetic, retarded, wasted, dirty, neglected patient readily gives the impression of suffering from a long-established cerebral degeneration rather than a curable disorder. The clue to the diagnosis is often to be found in a detailed and carefully taken history; but the patient may not be able to give such a history, and if he lives alone neither may anybody else. Fortunately, in the great majority of cases positive affective symptoms make the diagnosis possible; and depression is, in any case, less likely to be due to an organic disorder of the brain.

Annotations

CONFERENCE ON REMUNERATION

IT is now clear that the Working Party's report[1] on the future distribution of the central pool of remuneration is, in general, acceptable to doctors up and down the country. The Conference of Local Medical Committees that was held in London on June 26 was the culmination of a series of local constituency meetings called all over the country by members of the local medical committees. The Working Party must have been gratified to learn how acceptable their suggestions have proved. A surprisingly large number of local medical committees—some forty in all—sent in reports that they could accept all the recommendations. Other committees asked for clarification of certain sections and for assurances that the new distribution would not fail in its objective of bringing about "a relative improvement in the position of those practitioners least favourably placed under the present plan of distribution." In particular it was feared by some members of the Conference that practitioners who practised in areas where the practice size was often small and static, who had lists of 750 or less, and whose present income was augmented by a fixed annual payment, might find themselves no better off, or perhaps even worse off. This, it was suggested, might be avoided if a different range of 1000 patients (e.g., 251–1250) were chosen for the capitation load. The conference as a whole was satisfied that the load could most fairly be placed at the level of 501–1500 suggested by the Working Party, but accepted a motion from Cornwall that "provision be made for review of the success or otherwise of the new method of distribution with a view to further modification as found necessary in the light of experience." To this was added a rider, at the suggestion of Dr. S. Wand,

> "That if, when the new scheme of distribution has been endorsed by both parties, it is found in the light of experience that certain groups of practitioners who under the terms of reference of the Working Party might have expected to have benefited have, in fact, not done so, it be left to the Working Party provisionally to allocate an appropriate proportion of the final settlement monies for the purpose of remedying any obvious defects in the distribution scheme, such allocation to be subject to confirmation by the next Conference before it becomes a permanent feature of the scheme."

In the course of the discussions it was announced that in conversations at Somerset House an understanding had been reached that the income-tax assessable on the retrospective monies under the Danckwerts award would be "spread over the periods over which they are taken as having accrued." Where a doctor arranges himself to make a retrospective payment to an assistant it will be possible for him to charge this as part of his expenses for that particular year when his own retrospective receipts are assessed for tax. If a doctor has died before Parliament has eventually sanctioned the retrospective award, any monies that will accrue to his widow from the award will not be subject to payment of estate duties.

The Working Party's report has still to come before Parliament for approval; and the statement by the Parliamentary Labour Party, which we reproduce on p. 46, suggests that some of its terms will be keenly debated.

RADIOGRAPHY FOR THE ACUTE ABDOMEN

THE art of accurate diagnosis in acute abdominal disorders comes only with long experience. Nothing can replace the long apprenticeship in emergency surgery that is a feature of British surgical training. Of the ancillary aids to diagnosis, most are disappointing and some even misleading. To be sure it is helpful to know if there is pus in the urine; but many patients with pyuria have acute appendicitis. The white-cell count, as performed by the occasional leucocytologist in the hospital side-room, may be so inaccurate as to be almost valueless. What of the plain radiograph of the abdomen? On the whole, in the experience of most surgeons it is not of much help. In perforation of a hollow viscus air will be seen under the diaphragm if the picture is taken with the patient upright; but this is as a rule evident from the clinical examination. Opacities in the region of the gall-bladder and kidneys are likely to be misleading unless their appearance is very characteristic. Moreover, to depend on blurring of the renal and psoas shadows and on scoliosis for the diagnosis of a perinephric abscess is like photographing the sun to see if it is shining.

---

[1] See *Lancet*, 1952, i, 1147, 1155.

In intestinal obstruction, however, the plain film of the abdomen might be more extensively studied than it is at present, not so much for diagnosis (for this is usually obvious and nothing much is gained by seeing fluid levels on an X-ray film) as for localisation of the level of obstruction.

McLanahan et al.[1] have again drawn attention to the different gas pattern given by the different levels of the bowel. The transverse striations of the jejunum, the smooth loops of the ileum, and the segmented appearance of the colon are all characteristic. In high small-bowel obstructions only jejunal gas is visible; in ileal or right colonic obstruction there is jejunal and ileal gas and the descending colon is empty; in left-colon obstructions the gas shadows are present in the cæcum and transverse and descending colon, and little gas is present in the jejunum though ileal loops may be evident. The appearance of two enormous loops of bowel crossing the abdomen obliquely from the lower left to the upper right quadrant is pathognomonic of sigmoid volvulus. These radiographic signs are well known. Possibly, however, further study of the radiographic aspects of intestinal obstruction might bring still others to light.

SYRINGE-TRANSMITTED TUBERCULOSIS

It is well known that an imperfectly sterilised syringe or needle may convey infection from one patient to another; and, like other organisms, the tubercle bacillus may profit by some flaw in aseptic technique.

In 1946, Ebrill and Elek[2] treated a tuberculous abscess in a boy's thigh at the site where penicillin had been given by intramuscular drip, and came to the conclusion that tubercle bacilli had gained access either to the penicillin powder, to the diluted solution, or to the drip apparatus. Debré et al.[3] have reported 95 cases, 37 from the literature and 58 personal observations, of such primary tuberculosis. Of these, 78 had had penicillin injections; the remainder had received various substances, including physiological saline solution, soluble camphor, extract of artichoke leaves, various vaccines, salts of testosterone, vitamin C, and, paradoxically, streptomycin. There were 9 deaths, all in infants; 5 from generalised tuberculosis, 3 from intercurrent infections, and 1 from an unknown cause. The majority of infections occurred in chain epidemics. The abscess usually appeared within a fortnight of a subcutaneous or intramuscular injection (never after an intradermal one), and contained many tubercle bacilli (100 or more per microscope field) when the pus was examined within a month of infection. In all their own cases the organism was of the human type. A fistula developed and the regional lymph-glands were involved. The tuberculin reaction became positive after the usual ante-allergic period. Suppuration usually continued for a long time, to be followed by permanent recovery with a retracted scar. Complications included caseous abdominal glands (which tended to resolve), splenomegaly, hepatomegaly, discrete pleural effusions, nodular erythema, phlyctenular conjunctivitis, and spina ventosa. Treatment of the primary lesions with streptomycin did not give decisive results, but surgical drainage was effective.

Accidental inoculation of tubercle bacilli into the cellular tissue of children has results very similar to those obtained in guineapigs—nodules at the site of inoculation, adenitis, and fistula formation. The subcutaneous nodule appears at the end of the ante-allergic period, and successive guineapig inoculations during this period each produce a nodule evolving in the same way. But in children generalised tuberculosis is exceptional, while in the guineapig it is the rule.

Two explanations have been suggested for tuberculous abscesses in man: firstly, that infection is hæmatogenous and a hæmatoma at the injection site provides a focus for infection from a transient tuberculous bacteræmia; and, secondly, that the bacillus is introduced from without, either in the substance injected or from a contaminated syringe or needle.

Three cases have been recorded which support the hæmatogenous theory. In one a tuberculous abscess developed at the site of intramuscular injections of procaine.[4] Subsequent X-ray examination of the chest revealed pulmonary tuberculosis from which there possibly had been a hæmatogenous spread. In another a boy received an injection of penicillin into the buttock, and, two weeks later, injections into both thighs.[5] After a further three weeks a tuberculous abscess developed in the left thigh, followed by one in the right buttock. Later on, a spina ventosa was found in the right index finger. In the third case a child with pulmonary tuberculosis received a blow over the right supraorbital margin, where a tuberculous abscess later developed.[5]

But even if this mechanism was really responsible, it must be exceptional, for it has not been described after therapeutic injections in patients known to be tuberculous. Ebrill and Elek[2] could find no other tuberculous focus in their patient; and in the first 3 patients of Debré's series the tuberculin reaction was initially negative and became positive only after weeks or months.

It is most unlikely that the drug itself is infected, because so many different products have been involved and infections have occurred in several countries and seldom singly. The evidence that the infection is transmitted by the syringe is overwhelming. When a syringe is not disinfected between injections, tubercle bacilli may easily pass from patient to patient.

This mechanism was demonstrated by Debré and his colleagues[3] when they watched nurses giving penicillin injections. The penicillin in the bottle was dissolved in 20 ml. of physiological saline solution. A 2 ml. syringe filled with air was then fitted to the needle, air was introduced, and 2 ml. of penicillin withdrawn. The nurse then injected the solution into the indurated site of a previous injection in a child. At that moment the authors intervened. They emptied the syringe and filled it with saline solution, which then appeared slightly turbid. When it was injected into a guineapig an abscess containing tubercle bacilli formed at the point of inoculation 22 days later, and there was other evidence of tuberculosis. The implication is that the indurated area was a tuberculous focus. This procedure was repeated three times and on two occasions positive results were obtained. After an injection had been given to another child solid particles were seen floating in the syringe, and one of them contained tubercle bacilli.

Hughes[6] has demonstrated the reflux of tissue fluid into a syringe after an intramuscular injection, and this accounts for the presence of tuberculous material in the syringe after an injection into an infected focus.

There is therefore very strong evidence that the tubercle bacillus can enter the syringe during an injection. In other instances the syringe probably becomes accidentally contaminated during manipulations. The syringe and needle are the sources of danger, and they should be properly disinfected after every injection. Debré et al. found that boiling for 2–5 minutes usually destroyed all tubercle bacilli, but the time required was longer in the presence of oil, pus, or blood. Immersion in alcohol was useless. Fleming and Ogilvie[7] suggested that the risk of transmitting infection by syringes could be overcome by dipping the needle into liquid paraffin at 130°C for 10 seconds without removing the needle from the syringe. Boiling water was also effective, but the paraffin was preferable because it did not rust or blunt the needles. But this method has not, as far as we know,

been proved lethal to the tubercle bacillus, though it quickly and easily disposed of *Staphylococcus aureus*. Fleming and Ogilvie also concluded that reflux into the syringe did not take place if pressure was maintained on the piston until the needle was withdrawn; but if more than one injection was given from a single filling of the syringe, the contents might be contaminated.

RED CELLS IN ANIMALS

IT has been known for many years that animals show an inverse relation between the size of the red cells circulating in the peripheral blood and their number per unit volume of blood. Thus Wintrobe[1] pointed out that in vertebrates there is an extraordinary range of variation. At one end of the scale, the tailed amphibian, amphiuma, has a red-cell count of only 21,250 per c.mm., but the cells are immense—about 15,000 c.µ in volume. At the other end is the goat with a count of 18 million per c.mm., but a very small cell volume —about 19 c.µ. Similar variations can be found within animal families. These figures—taken from various sources—show the range for fishes:

	Red cells (million per c.mm.)	*Mean cell volume (c.µ)*
Hagfish (*Myxine glutinosa*)	0·15	1530
Clearnose Skate (*Raja eglanteria*)	0·30	823
Trout (*Salvelinus fontinalis*)	1·01	314
[illegible]	2·4	149
[illegible]	3·9	118
[illegible]	4·2	77

Wintrobe gives these figures for some more familiar animals:

	Red cells (million per c.mm.)	*Mean cell volume (c.µ)*
Dog	6·3	66
Cat	8	57
Mouse	9·3	49
Llama	15	25
Goat	17–18	16–19

All these figures show that the red-cell count is inversely proportional to cell volume. Wintrobe points out that this means that the amount of hæmoglobin available for the transport of oxygen is remarkably constant, though the size of the "packet" varies, and that evolutionary progress has favoured the smaller packets because they present, in sum, a greatly enlarged surface through which exchanges of gases and electrolytes can proceed more efficiently. Hartridge[2] showed that the red cell in the form of a biconcave disc has the most efficient shape for rapid gaseous exchange.

Wide variations have been reported in the red-cell counts of healthy domestic animals—variations not to be accounted for by experimental error, large though this is. For example, Wintrobe gives figures for the horse varying from 5·4 to 10·35 million per c.mm. Holman,[3] working at the Agricultural Research Council's field station at Compton in Berkshire, also noted these fluctuations, and he points out that they were found in apparently healthy farm animals of the same species. He quotes the observations of Rusoff and Piercy,[4] who found statistically significant differences in the red-cell counts of various dairy herds living in the same district. Holman observed, however, that the packed red-cell volumes varied much less than the red-cell counts.

Holman therefore set out to investigate the relation between the red-cell count, the packed-cell volume, and the mean cell volume in cows, sheep, goats, and horses. His results, based on a large number of observations, show quite clearly that there is a negative correlation between the red-cell count and the red-cell size (as shown by the mean cell volume) in all these animals. In other words, animals with counts *above* the average have corpuscles *below* average size, and vice versa. Individual cases did not keep strictly to this rule; for instance, in goats the lowest red-cell count recorded was 8·8 million per c.mm. and the highest 19·9 million, while the corresponding mean cell volumes were 23 c.µ and 16 c.µ. The smallest of all the mean cell volumes was 15 c.µ and the corresponding red-cell count was 18·9 million per c.mm. The greatest volume of 30 c.µ occurred in a goat with a count of 12·6 million.

Holman takes these observations as a warning against judging the state of the blood in farm animals by the red-cell count alone—a method that was abandoned long ago in examining human blood. He also points out that this variation must be taken into account when diagnosing macrocytic anæmia. But apart from these practical consequences, it is interesting to speculate why this variation, which, as we have seen, is a general feature in the animal world, is so striking among our domestic animals. Present-day domestic animals have a very complicated parentage; it may be worth seeing whether ancestry has any bearing on the size and number of red cells and on the relation between the two.

THE LISTER INSTITUTE

FROM time to time some particularly notable piece of medical research receives the full light of publicity, but in the main the work goes forward in relative obscurity. For every published investigation there are many preliminary and tentative, yet none the less vital, experiments which are known only to a few. The latest unobtrusive annual report from the Lister Institute of Preventive Medicine gives some inkling of the volume of work that is being done in just one research centre. True enough, there is an impressive list of scientific papers published from the laboratories of the institute in recent months, but it tells only a part of the story.

In the few pages they have allowed themselves, the governing body can do no more than mention the latest work. Among these allusions, often tantalisingly brief, we read that Dr. D. McClean, Mr. L. Vallet, and Dr. L. H. Collier are investigating the antigenicity of vaccinia virus that has been irradiated with ultraviolet light. Both vaccine lymph and purified elementary-body suspensions have been irradiated and completely inactivated so far as can be judged by tests on the rabbit's skin and on the embryonated egg. Rabbits immunised with these preparations are less susceptible to vaccination than normal rabbits, and they develop more virus-neutralising antibody. Further experiments are necessary to ensure that this apparent antigenic activity is not caused by small doses of living virus that have survived irradiation. If these results are confirmed and extended, preliminary immunisation with irradiated virus may provide a basal immunity that will modify the reaction to subsequent vaccination with living virus, and thus reduce its risks, particularly in primary vaccination in later life. Dr. W. d'A. Maycock and Miss L. L. Lorenz are studying the fate of dextran after intravenous injection, and a method has been developed for estimating dextran in urine and in aqueous tissue extracts. Most of the dextran which can be recovered from the tissues has been found in the liver, bone-marrow, lymph-glands, and spleen. It has also been observed that dextran is still excreted in the urine of the rabbit long after it can be detected serologically in the plasma. Sir Alan Drury, F.R.S., director of the institute, and Miss M. E. Blewett have been examining the various plasma-protein fractions for substances of biological interest. One fraction constricts the guineapig's intestine and also constricts perfused mammalian blood-vessels. Attempts are being made to discover the source of this substance. It is hoped that these observations may help to explain some of the effects of serum that have been known for many years but are as yet imperfectly understood. These

In intestinal obstruction, however, the plain film of the abdomen might be more extensively studied than it is at present, not so much for diagnosis (for this is usually obvious and nothing much is gained by seeing fluid levels on an X-ray film) as for localisation of the level of obstruction.

McLanahan et al.[1] have again drawn attention to the different gas pattern given by the different levels of the bowel. The transverse striations of the jejunum, the smooth loops of the ileum, and the segmented appearance of the colon are all characteristic. In high small-bowel obstructions only jejunal gas is visible; in ileal or right colonic obstruction there is jejunal and ileal gas and the descending colon is empty; in left-colon obstructions the gas shadows are present in the cæcum and transverse and descending colon, and little gas is present in the jejunum though ileal loops may be evident. The appearance of two enormous loops of bowel crossing the abdomen obliquely from the lower left to the upper right quadrant is pathognomonic of sigmoid volvulus. These radiographic signs are well known. Possibly, however, further study of the radiographic aspects of intestinal obstruction might bring still others to light.

SYRINGE-TRANSMITTED TUBERCULOSIS

It is well known that an imperfectly sterilised syringe or needle may convey infection from one patient to another; and, like other organisms, the tubercle bacillus may profit by some flaw in aseptic technique.

In 1946, Ebrill and Elek [2] treated a tuberculous abscess in a boy's thigh at the site where penicillin had been given by intramuscular drip, and came to the conclusion that tubercle bacilli had gained access either to the penicillin powder, to the diluted solution, or to the drip apparatus. Debré et al.[3] have reported 95 cases, 37 from the literature and 58 personal observations, of such primary tuberculosis. Of these, 78 had had penicillin injections; the remainder had received various substances, including physiological saline solution, soluble camphor, extract of artichoke leaves, various vaccines, salts of testosterone, vitamin C, and, paradoxically, streptomycin. There were 9 deaths, all in infants; 5 from generalised tuberculosis, 3 from intercurrent infections, and 1 from an unknown cause. The majority of infections occurred in chain epidemics. The abscess usually appeared within a fortnight of a subcutaneous or intramuscular injection (never after an intradermal one), and contained many tubercle bacilli (100 or more per microscope field) when the pus was examined within a month of infection. In all their own cases the organism was of the human type. A fistula developed and the regional lymph-glands were involved. The tuberculin reaction became positive after the usual ante-allergic period. Suppuration usually continued for a long time, to be followed by permanent recovery with a retracted scar. Complications included caseous abdominal glands (which tended to resolve), splenomegaly, hepatomegaly, discrete pleural effusions, nodular erythema, phlyctenular conjunctivitis, and spina ventosa. Treatment of the primary lesions with streptomycin did not give decisive results, but surgical drainage was effective.

Accidental inoculation of tubercle bacilli into the cellular tissue of children has results very similar to those obtained in guineapigs—nodules at the site of inoculation, adenitis, and fistula formation. The subcutaneous nodule appears at the end of the ante-allergic period, and successive guineapig inoculations during this period each produce a nodule evolving in the same way. But in children generalised tuberculosis is exceptional, while in the guineapig it is the rule.

Two explanations have been suggested for tuberculous abscesses in man: firstly, that infection is hæmatogenous and a hæmatoma at the injection site provides a focus for infection from a transient tuberculous bacteræmia; and, secondly, that the bacillus is introduced from without, either in the substance injected or from a contaminated syringe or needle.

Three cases have been recorded which support the hæmatogenous theory. In one a tuberculous abscess developed at the site of intramuscular injections of procaine.[4] Subsequent X-ray examination of the chest revealed pulmonary tuberculosis from which there possibly had been a hæmatogenous spread. In another a boy received an injection of penicillin into the buttock, and, two weeks later, injections into both thighs.[3] After a further three weeks a tuberculous abscess developed in the left thigh, followed by one in the right buttock. Later on, a spina ventosa was found in the right index finger. In the third case a child with pulmonary tuberculosis received a blow over the right supraorbital margin, where a tuberculous abscess later developed.[5]

But even if this mechanism was really responsible, it must be exceptional, for it has not been described after therapeutic injections in patients known to be tuberculous. Ebrill and Elek [2] could find no other tuberculous focus in their patient; and in the first 3 patients of Debré's series the tuberculin reaction was initially negative and became positive only after weeks or months.

It is most unlikely that the drug itself is infected, because so many different products have been involved and infections have occurred in several countries and seldom singly. The evidence that the infection is transmitted by the syringe is overwhelming. When a syringe is not disinfected between injections, tubercle bacilli may easily pass from patient to patient.

This mechanism was demonstrated by Debré and his colleagues [3] when they watched nurses giving penicillin injections. The penicillin in the bottle was dissolved in 20 ml. of physiological saline solution. A 2 ml. syringe filled with air was then fitted to the needle, air was introduced, and 2 ml. of penicillin withdrawn. The nurse then injected the solution into the indurated site of a previous injection in a child. At that moment the authors intervened. They emptied the syringe and filled it with saline solution, which then appeared slightly turbid. When it was injected into a guineapig an abscess containing tubercle bacilli formed at the point of inoculation 22 days later, and there was other evidence of tuberculosis. The implication is that the indurated area was a tuberculous focus. This procedure was repeated three times and on two occasions positive results were obtained. After an injection had been given to another child solid particles were seen floating in the syringe, and one of them contained tubercle bacilli.

Hughes [6] has demonstrated the reflux of tissue fluid into a syringe after an intramuscular injection, and this accounts for the presence of tuberculous material in the syringe after an injection into an infected focus.

There is therefore very strong evidence that the tubercle bacillus can enter the syringe during an injection. In other instances the syringe probably becomes accidentally contaminated during manipulations. The syringe and needle are the sources of danger, and they should be properly disinfected after every injection. Debré et al. found that boiling for 2–5 minutes usually destroyed all tubercle bacilli, but the time required was longer in the presence of oil, pus, or blood. Immersion in alcohol was useless. Fleming and Ogilvie [7] suggested that the risk of transmitting infection by syringes could be overcome by dipping the needle into liquid paraffin at 130°C for 10 seconds without removing the needle from the syringe. Boiling water was also effective, but the paraffin was preferable because it did not rust or blunt the needles. But this method has not, as far as we know,

RED CELLS IN ANIMALS

It has been known for many years that animals show an inverse relation between the size of the red cells circulating in the peripheral blood and their number per unit volume of blood. Thus Wintrobe[1] pointed out that in vertebrates there is an extraordinary range of variation. At one end of the scale, the tailed amphibian, amphiuma, has a red-cell count of only 21,250 per c.mm., but the cells are immense—about 15,000 c.μ in volume. At the other end is the goat with a count of 18 million per c.mm., but a very small cell volume —about 19 c.μ. Similar variations can be found within animal families. These figures—taken from various sources—show the range for fishes:

	Red cells (million per c.mm.)	*Mean cell volume (c.μ)*
Hagfish (*Myxine glutinosa*)	0·15	1530
Clearnose Skate (*Raja eglanteria*)	0·30	823
Trout (*Salvelinus fontinalis*)	1·01	314
Eel (*Anguilla bostoniensis*)	2·4	149
Mackerel (*Scomber scombrus*)	3·9	118
Puffer (*Spheroides maculatus*)	4·2	77

Wintrobe gives these figures for some more familiar animals:

	Red cells (million per c.mm.)	*Mean cell volume (c.μ)*
Dog	6·3	66
Cat	8	57
Mouse	9·3	49
Llama	15	25
Goat	17–18	16–19

All these figures show that the red-cell count is inversely proportional to cell volume. Wintrobe points out that this means that the amount of hæmoglobin available for the transport of oxygen is remarkably constant, though the size of the "packet" varies, and that evolutionary progress has favoured the smaller packets because they present, in sum, a greatly enlarged surface through which exchanges of gases and electrolytes can proceed more efficiently. Hartridge[2] showed that the red cell in the form of a biconcave disc has the most efficient shape for rapid gaseous exchange.

Wide variations have been reported in the red-cell counts of healthy domestic animals—variations not to be accounted for by experimental error, large though this is. For example, Wintrobe gives figures for the horse varying from 5·4 to 10·35 million per c.mm. Holman,[3] working at the Agricultural Research Council's field station at Compton in Berkshire, also noted these fluctuations, and he points out that they were found in apparently healthy farm animals of the same species. He quotes the observations of Rusoff and Piercy,[4] who found statistically significant differences in the red-cell counts of various dairy herds living in the same district. Holman observed, however, that the packed red-cell volumes varied much less than the red-cell counts.

Holman therefore set out to investigate the relation between the red-cell count, the packed-cell volume, and the mean cell volume in cows, sheep, goats, and horses. His results, based on a large number of observations, show quite clearly that there is a negative correlation between the red-cell count and the red-cell size (as shown by the mean cell volume) in all these animals. In other words, animals with counts *above* the average have corpuscles *below* average size, and vice versa. Individual cases did not keep strictly to this rule; for instance, in goats the lowest red-cell count recorded was 8·8 million per c.mm. and the highest 19·9 million, while the corresponding mean cell volumes were 23 c.μ and 16 c.μ. The smallest of all the mean cell volumes was 15 c.μ and the corresponding red-cell count was 18·9 million per c.mm. The greatest volume of 30 c.μ occurred in a goat with a count of 12·6 million.

Holman takes these observations as a warning against judging the state of the blood in farm animals by the red-cell count alone—a method that was abandoned long ago in examining human blood. He also points out that this variation must be taken into account when diagnosing macrocytic anæmia. But apart from these practical consequences, it is interesting to speculate why this variation, which, as we have seen, is a general feature in the animal world, is so striking among our domestic animals. Present-day domestic animals have a very complicated parentage; it may be worth seeing whether ancestry has any bearing on the size and number of red cells and on the relation between the two.

are only three of the many ways in which the institute continues as one of the foremost solvers of the biological jigsaw puzzle, many of whose perplexing pieces it has helped to put together in the past.

Much regret will be felt at the news that Sir Alan Drury is retiring, at the end of September, from the post of director which he has held since 1943. Despite all difficulties, his period of office has seen considerable developments at the institute, and his quiet wisdom and experience have been of great service both at the Lister itself and in the counsels of medical research.

ATMOSPHERIC CARCINOGENS

CHEMICAL compounds now known to be carcinogenic are numbered in hundreds; but so far only three—arsenic, benzpyrene, and radioactive substances—have been detected in notable quantities in atmospheric dust. These atmospheric carcinogens are discussed in the latest issue of the *British Journal of Cancer* [1–3] and in the report for 1951 of the British Empire Cancer Campaign.[4]

It has been found [1] that the arsenic content of the air in winter is twice that in summer; which suggests that the domestic combustion of coal is the chief source. The quantity of arsenic is, however, comparatively small; on the average the air breathed in a year by one person contains 0·5 mg., which is what might be found in 100 cigarettes. Waller [2] describes the estimation of benzpyrene in the smoke from eight different towns in England. As with arsenic, the concentration rises sharply in winter, and the mean annual value increases with the size of the town. Again the domestic fire appears to be the principal source. Benzpyrene has also been detected in the exhaust from internal-combustion engines, but in small amounts. It has not been found in cigarette smoke, but there seem to be considerable technical difficulties in detecting its presence there. Though it is now virtually certain that cigarette smoke is commonly carcinogenic, the fact remains that, judging by death certificates, the ratio of urban to rural cancer incidence in this country is of the order of two or three to one.[5] Much further information is needed before the part possibly played by benzpyrene can be assessed; it would be helpful to obtain data for lung cancer in localities where little coal is combusted, where the population does not smoke, where there are no exhaust fumes, and where there is nevertheless a good standard of hygiene and nutrition by present-day standards. Systematic elimination of these various factors should certainly yield interesting information.

Radioactivity in air dust [3] proved much the same in the heart of London, at Chiswick, at Rothamsted (a semi-rural district 30 miles from London), and in Manchester. Fluctuations in the activity at each site are attributed to varying weather conditions, the rate being higher when the ground is dry and the air still. The radioactivity in a cellar and in an air-raid shelter in London was remarkably high—up to 120 times as great as in the open air above the shelter. The floor dust was inactive, suggesting that the radioactive material is adsorbed on particles so small as to sink very slowly to floor level and that it has too short a life to accumulate on the floor. The very high activity in the shelter is ascribed to the lack of ventilation, which allows the radioactivity from the large wall area to accumulate in the suspended dust particles in the air. The highest value recorded in the shelter was, however, only one-eighth of the official tolerance dose. For comparison, the activity in the Joachimstaal mines is stated to be thirty times the tolerance dose. It is scarcely surprising, therefore, that in the past more than half the miners died of lung cancer.[6]

Whether atmospheric or dietetic carcinogens, the end-result of infective processes, or genetic changes are important factors in the rise of lung cancer has still to be decided. New carcinogens are being brought to light; for example, among workers in the chromate industry lung cancer is 16–80 times as common as in the general population, although chromate dust does not produce the disease in animals. Possibly carcinogens in trace amounts may reinforce each other's potency. Summation effects of this kind have already been described in clinical conditions (for instance, in xeroderma pigmentosum involving the human epidermis, where the two factors are a genetic one and sunlight) and in experimental carcinogenesis (for instance, dibenzanthracene-endosuccinate and X rays; methylcholanthrene, the Bittner virus, and a genetic factor; and dibenzanthracene and œstrone).

RETIREMENT OF DR. J. A. GLOVER

THE retirement of Dr. J. Alison Glover this week from the Ministry of Health, after $32^1/_2$ years' unbroken service with that Ministry and the Board of Education, marks the end of an epoch. The last of fourteen medical officers appointed by Dr. Addison just after the creation of the Ministry of Health, Dr. Glover is a direct link with an older age. His father, James Grey Glover, was a friend of Lord Lister and Sir John Simon, and as ethical adviser to THE LANCET exerted a wide influence over the policy of this journal for 37 years. Dr. Glover himself, as a dresser to Sir Henry Howse, carried out his dressings under a carbolic spray. He served with the infantry in the C.I.V. in 1900 and in the R.A.M.C. throughout the first world war, joining the Ministry of Health in 1920. From 1934 to 1941 he was senior medical officer at the Board of Education, and after his official retirement he re-joined the Ministry of Health to edit the annual reports of its Chief Medical Officer—"On the State of the Public Health"—and the Ministry's section of the *Monthly Bulletin of the Ministry of Health and Public Health Laboratory Service.* As we recorded at the time, he received last year the Jenner medal of the Royal Society of Medicine, of which he is an honorary fellow.

At a small private ceremony at the Ministry of Health last week Dr. Glover was presented with an 18th-century corner cupboard as a token of the affection in which he is held by all his colleagues.

ORTHOPÆDISTS MEET

THE first joint meeting of all the orthopædic associations of the English-speaking world opened in London last Monday in the presence of Queen Elizabeth the Queen Mother, who presented jewels of office to the presidents of visiting associations: Dr. Fremont Chandler (U.S.A.), Dr. R. Graham Huckell (Canada), Mr. Esmond West (Australia), Mr. Alexander Gillies (New Zealand), and Mr. G. du Toit (South Africa). Sir Reginald Watson-Jones, president of the British Orthopædic Association, read a telegram from the Queen, expressing her thanks for a message of good wishes. The scientific meetings were continuing for five days.

Welcoming delegates at a luncheon given by the Royal College of Surgeons after the inaugural ceremony, Sir Cecil Wakeley, P.R.C.S., remarked that the college is playing an ever-increasing part in postgraduate education and has instituted a joint committee for postgraduate orthopædic training, under the chairmanship of Sir Reginald Watson-Jones.

SIR PERCIVAL HORTON-SMITH HARTLEY, consulting physician to St. Bartholomew's Hospital, died in London on June 30, at the age of 84.

Points of View

A PHILOSOPHY OF HOSPITAL ADMINISTRATION*

STEPHEN TAYLOR
B.Sc., M.D. Lond., M.R.C.P.

ADMINISTRATION is simply an enabling process; it enables other people to get on with their jobs. This is no cause for shame, for the same is true of politics and all aspects of higher direction and government. In a completely wise society, we should be able to chop out these processes as unnecessary overheads. But in the imperfect world in which we live, the science and art of administration is forced into a key position by the technical complexities of society and the intellectual simplicity and emotional entanglements of the people who compose it.

Administration is a product of the large social group, which in turn is a product of technical and scientific advance and work-specialisation. The easy way of exploiting the marvels of factory production is to produce great concentrations of population. A dispersed factory population is possible, but men only learn its social and strategic value by bitter experience. Administration and the large social group march hand in hand. So we find administrators operating in large social groups of all kinds, at the hub of the megalopolis itself, and in each of the groups which compose it: in the factory, at the town hall, on the building site, in the newspaper office, at the pithead, in the film studio, at the traffic control point, in the government office, and, of course, in the hospital.

In each of these places unique work is being done. Sometimes by an engineer, a builder, or a surgeon; sometimes by a writer or creative artist, or some technical expert. This unique work is often both satisfying and exciting; for it is the field of creative craft and experimental advance. By comparison, administration is often tedious, repetitive, and dull. Indeed, the best justification for paying the administrator highly, compared with the technical expert, is that his work is so much more laborious, and so much less stimulating and satisfying. Nevertheless, the social value of administration in a modern society cannot be far behind the technical processes, for without administration there can be no large-scale technical activity.

COMMON FACTORS OF ADMINISTRATION

Wherever administration is needed, its basic technique is much the same, though administrators in each field are often concerned to prove that their particular job is unique. Usually this turns out to mean no more than the need for a smattering of technical knowledge, easily and swiftly acquired by an intelligent administrator from another field. I have tried to pick out the common factors in the administrative process.

Probably the most important are the multitude of *personal problems* and difficulties which arise in all large groups, and which it is the administrator's duty to disentangle and smooth out. These irritations may arise from genuine injustice or fabricated ill will; or they may be generated spontaneously by unhappy psychopaths, a proportion of whom must be carried in every group. Whatever their origin, it is easy to overrate their importance. The young administrator is at first overwhelmed and depressed by the volume and strength of the emotions with which he finds himself surrounded; but as he grows in wisdom and stature, so he learns to let them wash around him like a tide, secure in the knowledge that before many hours have passed the tide will have gone out again. The two great prophylactics in this field of human relations are selection and morale maintenance.

The next common factor in administration is the planning of *group structure* in its relation to function. Bound up with this is the level at which different types of decision ought to be taken. The bigger an organisation, the more complicated does its administration tend to become. Where peripheral units do a precisely similar routine job, tight central control is practicable—e.g., in Post Offices and National Insurance offices. But the more diverse local functions become, and the more varied the human needs which the service has to meet, the more paralysing is tight control from the centre. Not only is it paralysing, but it is also enormously wasteful. By detailed instruction central control attempts to make each peripheral unit capable of dealing with every eventuality. In practice, each peripheral unit has to deal with comparatively few of the possible eventualities, and these are best dealt with by a ready wit rather than a vast clutter of instructions and circulars. It is, I think, reasonable to lay down centrally very broad divisions of functions; it is convenient, also, to deal centrally with minimum wage and salary-rates, and conditions of service; but nothing more. Here, then, the keys to successful administration are broad central planning, coupled with almost complete peripheral autonomy.

Next come a group of common factors concerned with the *material facets* of any large organisation. There are premises, supplies, stores, rates and taxes, insurance, health of staff, and much else. I am by no means convinced that it is always necessary to subdivide functions here and to specialise excessively. Certainly the higher administrator should have had some "in the field" experience of all these activities, but in so far as they are professions in their own right I am in favour of calling in the expert, whether he be a surveyor, an income-tax consultant, or an industrial medical expert.

Imposed over all these varied activities is the controlling factor of *finance*. The bread-and-butter finance of the payment of wages, salaries, and bills, of records and balances, need not detain us. Our only concern is that it should be efficiently done, and that as few people as possible should have to spend their time in this necessary but sterile occupation. Finance, in its broader sense, is both a tool and a measuring instrument. It is a tool which will work miracles if it is applied at the right time and place. The art of buying, for quality as well as price, is one of the key actions in successful administration. Money wisely spent is what controls the environment in which we work. And we must always know how much we intend to spend on current consumption and maintenance, and how much on capital development. As a measuring instrument, financial analysis can show us precisely how we are deploying our forces, how much on each department, how much on each service cutting across departments, and how much on the overheads of administration. Costs must then be related to achievement, and so true cost can be determined. When this has been done, notional budgets are possible, against which to assess requirements and by means of which to devise equitable block grants.

In a hospital, measurement of achievement is not easy. What appears good at first sight may in fact be anything but good. A high rate of cure may be due to good work; but it may also be due to the admission of many mild cases and the rejection of severe cases. Two vital elements in estimating the achievement of a hospital are (1) the size of the community served, and (2) the overall recovery-rates in that community. Suppose the bed-costs of a hospital are high; that does not necessarily mean that the hospital is inefficient: it may be that it has a speedy turnover, and is successfully caring for many more patients than a cheaper and quieter hospital. Similarly, a high death-rate in a hospital does not necessarily mean bad work, for often a low death-rate in one hospital means a high death-rate somewhere else.

The hospital administrator, like the educational administrator and the county education officer, has two populations to deal with. There are the permanent "servers" (the nurses and doctors, or the school-are only three of the many ways in which the institute continues as one of the foremost solvers of the biological jigsaw puzzle, many of whose perplexing pieces it has helped to put together in the past.

---

* An address given to a weekend school of the Sheffield regional branch of the Institute of Hospital Administrators on April 19.

Much regret will be felt at the news that Sir Alan Drury is retiring, at the end of September, from the post of director which he has held since 1943. Despite all difficulties, his period of office has seen considerable developments at the institute, and his quiet wisdom and experience have been of great service both at the Lister itself and in the counsels of medical research.

ATMOSPHERIC CARCINOGENS

CHEMICAL compounds now known to be carcinogenic are numbered in hundreds; but so far only three—arsenic, benzpyrene, and radioactive substances—have been detected in notable quantities in atmospheric dust. These atmospheric carcinogens are discussed in the latest issue of the *British Journal of Cancer* [1–3] and in the report for 1951 of the British Empire Cancer Campaign.[4]

It has been found [1] that the arsenic content of the air in winter is twice that in summer; which suggests that the domestic combustion of coal is the chief source. The quantity of arsenic is, however, comparatively small; on the average the air breathed in a year by one person contains 0·5 mg., which is what might be found in 100 cigarettes. Waller [2] describes the estimation of benzpyrene in the smoke from eight different towns in England. As with arsenic, the concentration rises sharply in winter, and the mean annual value increases with the size of the town. Again the domestic fire appears to be the principal source. Benzpyrene has also been detected in the exhaust from internal-combustion engines, but in small amounts. It has not been found in cigarette smoke, but there seem to be considerable technical difficulties in detecting its presence there. Though it is now virtually certain that cigarette smoke is commonly carcinogenic, the fact remains that, judging by death certificates, the ratio of urban to rural cancer incidence in this country is of the order of two or three to one.[5] Much further information is needed before the part possibly played by benzpyrene can be assessed; it would be helpful to obtain data for lung cancer in localities where little coal is combusted, where the population does not smoke, where there are no exhaust fumes, and where there is nevertheless a good standard of hygiene and nutrition by present-day standards. Systematic elimination of these various factors should certainly yield interesting information.

Radioactivity in air dust [3] proved much the same in the heart of London, at Chiswick, at Rothamsted (a semi-rural district 30 miles from London), and in Manchester. Fluctuations in the activity at each site are attributed to varying weather conditions, the rate being higher when the ground is dry and the air still. The radioactivity in a cellar and in an air-raid shelter in London was remarkably high—up to 120 times as great as in the open air above the shelter. The floor dust was inactive, suggesting that the radioactive material is adsorbed on particles so small as to sink very slowly to floor level and that it has too short a life to accumulate on the floor. The very high activity in the shelter is ascribed to the lack of ventilation, which allows the radioactivity from the large wall area to accumulate in the suspended dust particles in the air. The highest value recorded in the shelter was, however, only one-eighth of the official tolerance dose. For comparison, the activity in the Joachimstaal mines is stated to be thirty times the tolerance dose. It is scarcely surprising, therefore, that in the past more than half the miners died of lung cancer.[6]

Whether atmospheric or dietetic carcinogens, the end-result of infective processes, or genetic changes are important factors in the rise of lung cancer has still to be decided. New carcinogens are being brought to light; for example, among workers in the chromate industry lung cancer is 16–80 times as common as in the general population, although chromate dust does not produce the disease in animals. Possibly carcinogens in trace amounts may reinforce each other's potency. Summation effects of this kind have already been described in clinical conditions (for instance, in xeroderma pigmentosum involving the human epidermis, where the two factors are a genetic one and sunlight) and in experimental carcinogenesis (for instance, dibenzanthracene endosuccinate and X rays; methylcholanthrene, the Bittner virus, and a genetic factor; and dibenzanthracene and œstrone).

RETIREMENT OF DR. J. A. GLOVER

THE retirement of Dr. J. Alison Glover this week from the Ministry of Health, after 32½ years' unbroken service with that Ministry and the Board of Education, marks the end of an epoch. The last of fourteen medical officers appointed by Dr. Addison just after the creation of the Ministry of Health, Dr. Glover is a direct link with an older age. His father, James Grey Glover, was a friend of Lord Lister and Sir John Simon, and as ethical adviser to THE LANCET exerted a wide influence over the policy of this journal for 37 years. Dr. Glover himself, as a dresser to Sir Henry Howse, carried out his dressings under a carbolic spray. He served with the infantry in the C.I.V. in 1900 and in the R.A.M.C. throughout the first world war, joining the Ministry of Health in 1920. From 1934 to 1941 he was senior medical officer at the Board of Education, and after his official retirement he re-joined the Ministry of Health to edit the annual reports of its Chief Medical Officer—"On the State of the Public Health"—and the Ministry's section of the *Monthly Bulletin of the Ministry of Health and Public Health Laboratory Service*. As we recorded at the time, he received last year the Jenner medal of the Royal Society of Medicine, of which he is an honorary fellow.

At a small private ceremony at the Ministry of Health last week Dr. Glover was presented with an 18th-century corner cupboard as a token of the affection in which he is held by all his colleagues.

ORTHOPÆDISTS MEET

THE first joint meeting of all the orthopædic associations of the English-speaking world opened in London last Monday in the presence of Queen Elizabeth the Queen Mother, who presented jewels of office to the presidents of visiting associations: Dr. Fremont Chandler (U.S.A.), Dr. R. Graham Huckell (Canada), Mr. Esmond West (Australia), Mr. Alexander Gillies (New Zealand), and Mr. G. du Toit (South Africa). Sir Reginald Watson-Jones, president of the British Orthopædic Association, read a telegram from the Queen, expressing her thanks for a message of good wishes. The scientific meetings were continuing for five days.

Welcoming delegates at a luncheon given by the Royal College of Surgeons after the inaugural ceremony, Sir Cecil Wakeley, P.R.C.S., remarked that the college is playing an ever-increasing part in postgraduate education and has instituted a joint committee for postgraduate orthopædic training, under the chairmanship of Sir Reginald Watson-Jones.

Sir PERCIVAL HORTON-SMITH HARTLEY, consulting physician to St. Bartholomew's Hospital, died in London on June 30, at the age of 84.

Points of View

A PHILOSOPHY OF HOSPITAL ADMINISTRATION*

STEPHEN TAYLOR
B.Sc., M.D. Lond., M.R.C.P.

ADMINISTRATION is simply an enabling process; it enables other people to get on with their jobs. This is no cause for shame, for the same is true of politics and all aspects of higher direction and government. In a completely wise society, we should be able to chop out these processes as unnecessary overheads. But in the imperfect world in which we live, the science and art of administration is forced into a key position by the technical complexities of society and the intellectual simplicity and emotional entanglements of the people who compose it.

Administration is a product of the large social group, which in turn is a product of technical and scientific advance and work-specialisation. The easy way of exploiting the marvels of factory production is to produce great concentrations of population. A dispersed factory population is possible, but men only learn its social and strategic value by bitter experience. Administration and the large social group march hand in hand. So we find administrators operating in large social groups of all kinds, at the hub of the megalopolis itself, and in each of the groups which compose it: in the factory, at the town hall, on the building site, in the newspaper office, at the pithead, in the film studio, at the traffic control point, in the government office, and, of course, in the hospital.

In each of these places unique work is being done. Sometimes by an engineer, a builder, or a surgeon; sometimes by a writer or creative artist, or some technical expert. This unique work is often both satisfying and exciting; for it is the field of creative craft and experimental advance. By comparison, administration is often tedious, repetitive, and dull. Indeed, the best justification for paying the administrator highly, compared with the technical expert, is that his work is so much more laborious, and so much less stimulating and satisfying. Nevertheless, the social value of administration in a modern society cannot be far behind the technical processes, for without administration there can be no large-scale technical activity.

COMMON FACTORS OF ADMINISTRATION

Wherever administration is needed, its basic technique is much the same, though administrators in each field are often concerned to prove that their particular job is unique. Usually this turns out to mean no more than the need for a smattering of technical knowledge, easily and swiftly acquired by an intelligent administrator from another field. I have tried to pick out the common factors in the administrative process.

Probably the most important are the multitude of *personal problems* and difficulties which arise in all large groups, and which it is the administrator's duty to disentangle and smooth out. These irritations may arise from genuine injustice or fabricated ill will; or they may be generated spontaneously by unhappy psychopaths, a proportion of whom must be carried in every group. Whatever their origin, it is easy to overrate their importance. The young administrator is at first overwhelmed and depressed by the volume and strength of the emotions with which he finds himself surrounded; but as he grows in wisdom and stature, so he learns to let them wash around him like a tide, secure in the knowledge that before many hours have passed the tide will have gone out again. The two great prophylactics in this field of human relations are selection and morale maintenance.

The next common factor in administration is the planning of *group structure* in its relation to function. Bound up with this is the level at which different types of decision ought to be taken. The bigger an organisation, the more complicated does its administration tend to become. Where peripheral units do a precisely similar routine job, tight central control is practicable—e.g., in Post Offices and National Insurance offices. But the more diverse local functions become, and the more varied the human needs which the service has to meet, the more paralysing is tight control from the centre. Not only is it paralysing, but it is also enormously wasteful. By detailed instruction central control attempts to make each peripheral unit capable of dealing with every eventuality. In practice, each peripheral unit has to deal with comparatively few of the possible eventualities, and these are best dealt with by a ready wit rather than a vast clutter of instructions and circulars. It is, I think, reasonable to lay down centrally very broad divisions of functions; it is convenient, also, to deal centrally with minimum wage and salary-rates, and conditions of service; but nothing more. Here, then, the keys to successful administration are broad central planning, coupled with almost complete peripheral autonomy.

Next come a group of common factors concerned with the *material facets* of any large organisation. There are premises, supplies, stores, rates and taxes, insurance, health of staff, and much else. I am by no means convinced that it is always necessary to subdivide functions here and to specialise excessively. Certainly the higher administrator should have had some "in the field" experience of all these activities, but in so far as they are professions in their own right I am in favour of calling in the expert, whether he be a surveyor, an income-tax consultant, or an industrial medical expert.

Imposed over all these varied activities is the controlling factor of *finance*. The bread-and-butter finance of the payment of wages, salaries, and bills, of records and balances, need not detain us. Our only concern is that it should be efficiently done, and that as few people as possible should have to spend their time in this necessary but sterile occupation. Finance, in its broader sense, is both a tool and a measuring instrument. It is a tool which will work miracles if it is applied at the right time and place. The art of buying, for quality as well as price, is one of the key actions in successful administration. Money wisely spent is what controls the environment in which we work. And we must always know how much we intend to spend on current consumption and maintenance, and how much on capital development. As a measuring instrument, financial analysis can show us precisely how we are deploying our forces, how much on each department, how much on each service cutting across departments, and how much on the overheads of administration. Costs must then be related to achievement, and so true cost can be determined. When this has been done, notional budgets are possible, against which to assess requirements and by means of which to devise equitable block grants.

In a hospital, measurement of achievement is not easy. What appears good at first sight may in fact be anything but good. A high rate of cure may be due to good work; but it may also be due to the admission of many mild cases and the rejection of severe cases. Two vital elements in estimating the achievement of a hospital are (1) the size of the community served, and (2) the overall recovery-rates in that community. Suppose the bed-costs of a hospital are high; that does not necessarily mean that the hospital is inefficient: it may be that it has a speedy turnover, and is successfully caring for many more patients than a cheaper and quieter hospital. Similarly, a high death-rate in a hospital does not necessarily mean bad work, for often a low death-rate in one hospital means a high death-rate somewhere else.

The hospital administrator, like the educational administrator and the county education officer, has two populations to deal with. There are the permanent "servers" (the nurses and doctors, or the school-teachers) and the transitory "served" (the patients or the school-children). The manufacturer, the building contractor, and the Civil Servant also have this second population; but their consumers are not concentrated under a common roof.

---

* An address given to a weekend school of the Sheffield regional branch of the Institute of Hospital Administrators on April 19.

Indeed, the only peculiarities I can discover in hospital administration spring from its relation with illness and the emotions which illness arouses, and its relation with the *most affluent and powerful of all professions* in modern society—the medical profession. In a sense, the hospital administrator is less a master in his own house then any other administrator; though more and more the technicians in other walks of life are giving the administrator a run for his money.

ADMINISTRATIVE VICES AND VIRTUES

My own attitude to administrators depends on the behaviour of the last with whom I have had dealings. Their range is extraordinary, from the bottom of the barrel of humanity to the top. The great administrator is a great creative artist; because his medium is the lives of other people, the outline of the picture he is painting may be a little obscured, but *it can live as truly as any* other work of art. The good administrator is less spectacular but he is of vital importance to society; he may mould less, but sometimes this may be a powerful virtue. The bad administrator varies from being a nuisance to a menace; while the evil administrator is a creator of frustration, hatred, and malice, a person more pernicious than the *criminal operating against property* or even life, because he is beyond the arm of the law. The two extremes are rare, but these potentialities for good or evil are within most of us.

Administration carries a special mental occupational risk, for it is concerned with power. It is quite untrue to say that all power corrupts; but it is true that many people are more easily corrupted by power than anything else. All who practise administration must keep watch against this subtle corruption.

The first symptom is "important-itis." It is often seen in some young clerk or executive, a promising worker who is rewarded by promotion; one catches him shouting at a nurse, giving orders to a sister old enough to be his mother, or by his rudeness reducing the patient's wife to tears. Closely linked with this type of bumptiousness is the overcompensated second-rater who hides his defects in blustering self-importance.

One of the diagnostic features of the administrator who is too small for his job is the inflated team which he creates, immediately responsible to himself. He fails to realise that true administrative virtue is measured by the smallness, rather than the largeness, of the staff needed for any job.

The last two vices of administrators I shall mention are the top and bottom ends of the same curve of normal distribution. We all know the over-administrator who is continually poking and prying into the work of subordinates and technical colleagues. Over-administration is a fault to which many good administrators are prone; unhappily, experience often proves it to be necessary as a spur and stimulus to those administered. The alternative, the other side of the penny as it were, is administrative laziness, which is perhaps the greater failing. As it so often turns out, true administrative wisdom is to be found in the happy medium.

True humility I would put as the first and cardinal virtue of the administrator. By this I mean neither sloppy tolerance nor feeble discipline, but rather the realisation of the basic unimportance of the process of administration, and the basic equality of all of us in the last ethical analysis. True humility leaves no room for snobbishness, pomposity, a false sense of values, and magnification of the trivial. Above all, it puts the patient at the centre of the picture. The only excuse for the existence of doctors and nurses is the existence of the patient, and the hospital administrator exists only to enable doctors and nurses to care for the patient.

As a corrective to administrative *pride*, I like to imagine a congress of administrators meeting aboard a luxury liner. A great storm arises and the liner is wrecked on a desert island. None but the administrators survive. Imagine the consternation. There is real work to be *done!* The recording of minutes, the taking of decisions, the delegation of functions, will no longer suffice. He who will not work with his hands neither will he eat. Imagine the fresh evaluation of society which would follow. The key men would now be the amateur gardeners, farmers, and first-aiders. The one occupation for which there would be no call would be administration.

Yet there are some administrators, both outside and inside official service, who by their inherent excellence would rise like cream to the top of any society. Such men and women would shine no less in the search for food, clothes, and shelter on a desert island than they do in our complex civilisation. On the whole, I think they are more often found in private than in public enterprise, *though this is less true than it was.*

Such people are the creative adventurers of our society. It is they who make things happen. It is their magic touch which builds the social and economic units of our society, whether such units are factories, shops, housing estates, schools, colleges, or even hospitals.

ADVENTURERS AND MAINTAINERS

The creative adventurer must possess three things: first, the intellectual capacity for creation; second, the driving force, the *élan vital*, without which nothing happens; third, the spirit of adventure, the love of battle and the fight for its own sake, the thrill of taking the risk and the nice calculation of the risk taken.

The *capacity for creation* is a complex of mental facets. Analytical intellectual activity may be a positive disadvantage; barristers are seldom builders, and it is a criticism of the higher Civil Service that it relies too much on analytical capacity and too little on creative ability. At first sight these creators may seem to lack basic intelligence. But this may be no more than an expression of their lack of interest in spheres of life which they have dismissed as unimportant or outside their field of activity. Sometimes their contempt for intellectual activity is an expression of their age of school-leaving. Many a creator regards school activities as boring and divorced from reality.

The *æsthetics* of social and economic creation are *practised intuitively rather than explicitly.* Many of the physical defects of our society may be traced to the lack of social taste in the age in which the creative adventurer rose to maturity. The builder must have his vision, but that vision will be determined by the society in which he lives. For it will always be capable of interpretation in terms of everyday reality. It will, however, be no static vision; it will evolve in the light of experience and change with its changing environment. The satisfaction of this æsthetic urge comes in the building rather than in the final product. Once the edifice is made, this type of creative artist will slip away to try his hand in a different field.

The creative adventurer is a man of both *speech* and *action*. He is seldom to be found in his office, and indeed, the best administrator is often *the least* office-bound; clerical work should be delegated to clerks, and not undertaken by the administrator. The volubility of the creative adventurer may make it difficult to distinguish him from his disreputable first-cousin, the huckster on his market stall, the confidence trickster, the windbag and the humbug, who sometimes manages to foist himself on the unsuspecting selection committee. The simplest test to distinguish the true from the false, the solid building from the empty façade, is to see if the talker is equally prepared to listen and learn.

The *driving force* of the creative adventurer is often phasic in its manifestations. Though there must be a measure of perseverance, the creative act is essentially rhythmic and mercurial. The energy output cannot be maintained all the time, and there must be periods of quiet build-up when nothing much happens. Then a threshold is reached and he is off once more. He bangs into his environment; his aim is to give better than he gets, to mould rather than to be moulded.

The *spirit of adventure* expresses itself most clearly in a readiness to take risks and delight in so doing. He has an attitude of sturdy independence to authority, a regard for the law based on the spirit rather than the letter, and no great thought for the morrow in terms of present security. It is the exact opposite of respectability, of playing for safety, of "pension-itis," and all the other signs of a desire to gain security in a changing world and sell one's soul for a mess of rather dull pottage.

That, then, is a picture of one type of great administrator. In a sense it is both incomplete and over-complete, for no-one will fit precisely into the pattern. There are, however, other pictures of administrative excellence. There are the maintainers, the great exponents of the holding action, who "keep right on to the end of the road" at a slower and less hectic pace. They are less likely to create, but are more likely to hold fast to what is good. They, too, must be intelligent, with an even temper, patience, and humour. They must be able to pick out the essential from the inessential; indeed one of the secrets of good administration is to eliminate everything extraneous or unimportant from any problem or situation.

HUMAN PROBLEMS OF ADMINISTRATION

In many human situations administrative action can convert unhappiness into happiness. It is a good principle always to stretch a point in favour of the individual, and in particular in favour of the freedom of the individual. The petty tyrant is the great author of the unnecessary negative.

But most human problems in administration are far less tangible. They are, in the main, the products of unsatisfied emotion. By this I do not mean cattiness or waspishness, though this does occur, but rather unused emotion in people of both sexes, people in whom part of the trouble is that they are underworked.

There are simple remedies for this. It is as well always to aim at being slightly understaffed, so that everyone always has plenty of real work to do. If by overtime it is possible to avoid the employment of more staff, then overtime is socially desirable, provided it does not mean skimping work during real time, and provided it is not pushed so far as to produce inefficiency through fatigue.

The other great remedy is to build up and maintain staff morale. Everyone should feel that his or her job is really worth while, and that the hospital as a whole is moving steadily forward in service. The citizens of any community should have faith in their hospitals and feel proud of them. They will do so precisely in proportion to the pride which the hospital workers feel in themselves and their work. Once good morale has been built up, staff recruitment becomes comparatively easy. Personal smartness of the staff is important; the hospital or institution which issues its porters with uniforms which cannot look well is making a shortsighted economy. Slovenliness in porters and servants, and rude offhandedness in clerks and officials, should be jumped on at once. If they are allowed to pass, they become infectious and the whole tone of the place is lowered. But coupled with justifiable pride must be an ultimate humility; for it is from humility that all humanity stems. Indeed, the nice balance of pride and humility is the basis of good morale.

The administrator who despises staff negotiating machinery is foolishly shortsighted. Often negotiations are piffling in themselves; in fact, they are then acting as an emotional safety-valve. They are also a training in occupational democracy, and sometimes they may even be of real value in righting genuine wrongs. Their final use is as a means of dealing with the complaining psychopath, a curse inside any organisation. Once the complaints of the psychopath get into the official machine there is every hope of their being able to travel up and down for years without harming anyone.

ADMINISTRATORS AND DOCTORS

Perhaps the greatest difficulty which faces the hospital administrator is his relationship with the doctors. It is a subtle and difficult one. The medical man who decides to become a hospital administrator is, in this country at any rate, in a worse position than the layman. Other doctors tend to regard his decision as one dictated by lack of clinical skill, and they will dispute his administrative decisions simply because they resent the possibility that they may be based on medical knowledge. On the whole, therefore, I am in favour of the lay administrator; but it may sometimes happen that a medical man proves himself to be supremely competent in administration, and our system should be sufficiently flexible to make use of such exceptions to any general rule.

One of the great advances brought by the National Health Service has been the abolition of medical hierarchy in hospital as it was seen in most local-authority hospitals, and as it is still seen in some Service hospitals. The substitution of a number of parallel teams, units, or firms gives to the senior doctors complete clinical autonomy, without which, in my view, good medicine cannot be practised. The new liberty and equality take getting used to. The fraternity needed is not always forthcoming, and the need does sometimes arise for a measure of discipline, to correct either laziness or clinical failings on the medical side. I have no doubt that such discipline can only be a self-discipline applied by the medical profession itself.

The question is, how should it be applied? What is the best technique? The medical staff committee is a useful device, but only sometimes will its chairman feel that he has the necessary authority to administer a correction to his colleagues. Where his personality is such that he is able to do this, I have no doubt that he is the right ally for the lay administrator.

The Americans seem to have adopted a good system, whereby the chief of each department is known as a "chief of service." These chiefs of service form a medical board, and one of them is elected its president. The board meets weekly to perform an audit of service in the hospital, and any medical failures are investigated before the board and, if need be, correction is administered. The medical board is the police machine for the medical side of the hospital, and it looks as though it works effectively. It would be an interesting experiment to see such boards tried in a few English hospitals; save on the rarest occasions, it is not part of the job of the medical committee to investigate the failings of medical staff, yet healthy self-criticism inside each hospital might do a lot of good.

I am quite sure it is wrong to try to establish any other kind of supervising machinery for the doctors. Good medicine demands the occasional taking of risks, and those risks must be taken in the interest of the patient without regard to possible subsequent lay criticism. The doctor who is always looking over his shoulder at some other authority is certain to be a bad doctor.

If administrators are varied in their personalities, so too are the doctors. And doctors, like administrators, are subject to special occupational risks. Doctors may be brusque and rude at times; above all they may exhibit contempt for lay authorities. This is entirely healthy. Their job is to serve their patients, and not toady to committees or officialdom. The doctor who successfully squirms his way into the good graces of the lay authorities teachers) and the transitory "served" (the patients or the school-children). The manufacturer, the building contractor, and the Civil Servant also have this second population; but their consumers are not concentrated under a common roof.

Indeed, the only peculiarities I can discover in hospital administration spring from its relation with illness and the emotions which illness arouses, and its relation with the most affluent and powerful of all professions in modern society—the medical profession. In a sense, the hospital administrator is less a master in his own house then any other administrator; though more and more the technicians in other walks of life are giving the administrator a run for his money.

ADMINISTRATIVE VICES AND VIRTUES

My own attitude to administrators depends on the behaviour of the last with whom I have had dealings. Their range is extraordinary, from the bottom of the barrel of humanity to the top. The great administrator is a great creative artist; because his medium is the lives of other people, the outline of the picture he is painting may be a little obscured, but it can live as truly as any other work of art. The good administrator is less spectacular but he is of vital importance to society; he may mould less, but sometimes this may be a powerful virtue. The bad administrator varies from being a nuisance to a menace; while the evil administrator is a creator of frustration, hatred, and malice, a person more pernicious than the criminal operating against property or even life, because he is beyond the arm of the law. The two extremes are rare, but these potentialities for good or evil are within most of us.

Administration carries a special mental occupational risk, for it is concerned with power. It is quite untrue to say that all power corrupts; but it is true that many people are more easily corrupted by power than anything else. All who practise administration must keep watch against this subtle corruption.

The first symptom is "important-itis." It is often seen in some young clerk or executive, a promising worker who is rewarded by promotion; one catches him shouting at a nurse, giving orders to a sister old enough to be his mother, or by his rudeness reducing the patient's wife to tears. Closely linked with this type of bumptiousness is the overcompensated second-rater who hides his defects in blustering self-importance.

One of the diagnostic features of the administrator who is too small for his job is the inflated team which he creates, immediately responsible to himself. He fails to realise that true administrative virtue is measured by the smallness, rather than the largeness, of the staff needed for any job.

The last two vices of administrators I shall mention are the top and bottom ends of the same curve of normal distribution. We all know the over-administrator who is continually poking and prying into the work of subordinates and technical colleagues. Over-administration is a fault to which many good administrators are prone; unhappily, experience often proves it to be necessary as a spur and stimulus to those administered. The alternative, the other side of the penny as it were, is administrative laziness, which is perhaps the greater failing. As it so often turns out, true administrative wisdom is to be found in the happy medium.

True humility I would put as the first and cardinal virtue of the administrator. By this I mean neither sloppy tolerance nor feeble discipline, but rather the realisation of the basic unimportance of the process of administration, and the basic equality of all of us in the last ethical analysis. True humility leaves no room for snobbishness, pomposity, a false sense of values, and magnification of the trivial. Above all, it puts the patient at the centre of the picture. The only excuse for the existence of doctors and nurses is the existence of the patient, and the hospital administrator exists only to enable doctors and nurses to care for the patient.

As a corrective to administrative pride, I like to imagine a congress of administrators meeting aboard a luxury liner. A great storm arises and the liner is wrecked on a desert island. None but the administrators survive. Imagine the consternation. There is real work to be done! The recording of minutes, the taking of decisions, the delegation of functions, will no longer suffice. He who will not work with his hands neither will he eat. Imagine the fresh evaluation of society which would follow. The key men would now be the amateur gardeners, farmers, and first-aiders. The one occupation for which there would be no call would be administration.

Yet there are some administrators, both outside and inside official service, who by their inherent excellence would rise like cream to the top of any society. Such men and women would shine no less in the search for food, clothes, and shelter on a desert island than they do in our complex civilisation. On the whole, I think they are more often found in private than in public enterprise, though this is less true than it was.

Such people are the creative adventurers of our society. It is they who make things happen. It is their magic touch which builds the social and economic units of our society, whether such units are factories, shops, housing estates, schools, colleges, or even hospitals.

ADVENTURERS AND MAINTAINERS

The creative adventurer must possess three things: first, the intellectual capacity for creation; second, the driving force, the *élan vital*, without which nothing happens; third, the spirit of adventure, the love of battle and the fight for its own sake, the thrill of taking the risk and the nice calculation of the risk taken.

The *capacity for creation* is a complex of mental facets. Analytical intellectual activity may be a positive disadvantage; barristers are seldom builders, and it is a criticism of the higher Civil Service that it relies too much on analytical capacity and too little on creative ability. At first sight these creators may seem to lack basic intelligence. But this may be no more than an expression of their lack of interest in spheres of life which they have dismissed as unimportant or outside their field of activity. Sometimes their contempt for intellectual activity is an expression of their age of school-leaving. Many a creator regards school activities as boring and divorced from reality.

The *æsthetics* of social and economic creation are practised intuitively rather than explicitly. Many of the physical defects of our society may be traced to the lack of social taste in the age in which the creative adventurer rose to maturity. The builder must have his vision, but that vision will be determined by the society in which he lives. For it will always be capable of interpretation in terms of everyday reality. It will, however, be no static vision; it will evolve in the light of experience and change with its changing environment. The satisfaction of this æsthetic urge comes in the building rather than in the final product. Once the edifice is made, this type of creative artist will slip away to try his hand in a different field.

The creative adventurer is a man of both *speech* and *action*. He is seldom to be found in his office, and indeed, the best administrator is often the least office-bound; clerical work should be delegated to clerks, and not undertaken by the administrator. The volubility of the creative adventurer may make it difficult to distinguish him from his disreputable first-cousin, the huckster on his market stall, the confidence trickster, the windbag and the humbug, who sometimes manages to foist himself on the unsuspecting selection committee. The simplest test to distinguish the true from the false, the solid building from the empty façade, is to see if the talker is equally prepared to listen and learn.

The *driving force* of the creative adventurer is often phasic in its manifestations. Though there must be a measure of perseverance, the creative act is essentially rhythmic and mercurial. The energy output cannot be maintained all the time, and there must be periods of quiet build-up when nothing much happens. Then a threshold is reached and he is off once more. He bangs into his environment; his aim is to give better than he gets, to mould rather than to be moulded.

The *spirit of adventure* expresses itself most clearly in a readiness to take risks and delight in so doing. He has an attitude of sturdy independence to authority, a regard for the law based on the spirit rather than the letter, and no great thought for the morrow in terms of present security. It is the exact opposite of respectability, of playing for safety, of "pension-itis," and all the other signs of a desire to gain security in a changing world and sell one's soul for a mess of rather dull pottage.

That, then, is a picture of one type of great administrator. In a sense it is both incomplete and over-complete, for no-one will fit precisely into the pattern. There are, however, other pictures of administrative excellence. There are the maintainers, the great exponents of the holding action, who "keep right on to the end of the road" at a slower and less hectic pace. They are less likely to create, but are more likely to hold fast to what is good. They, too, must be intelligent, with an even temper, patience, and humour. They must be able to pick out the essential from the inessential; indeed one of the secrets of good administration is to eliminate everything extraneous or unimportant from any problem or situation.

HUMAN PROBLEMS OF ADMINISTRATION

In many human situations administrative action can convert unhappiness into happiness. It is a good principle always to stretch a point in favour of the individual, and in particular in favour of the freedom of the individual. The petty tyrant is the great author of the unnecessary negative.

But most human problems in administration are far less tangible. They are, in the main, the products of unsatisfied emotion. By this I do not mean cattiness or waspishness, though this does occur, but rather unused emotion in people of both sexes, people in whom part of the trouble is that they are underworked.

There are simple remedies for this. It is as well always to aim at being slightly understaffed, so that everyone always has plenty of real work to do. If by overtime it is possible to avoid the employment of more staff, then overtime is socially desirable, provided it does not mean skimping work during real time, and provided it is not pushed so far as to produce inefficiency through fatigue.

The other great remedy is to build up and maintain staff morale. Everyone should feel that his or her job is really worth while, and that the hospital as a whole is moving steadily forward in service. The citizens of any community should have faith in their hospitals and feel proud of them. They will do so precisely in proportion to the pride which the hospital workers feel in themselves and their work. Once good morale has been built up, staff recruitment becomes comparatively easy. Personal smartness of the staff is important; the hospital or institution which issues its porters with uniforms which cannot look well is making a shortsighted economy. Slovenliness in porters and servants, and rude offhandedness in clerks and officials, should be jumped on at once. If they are allowed to pass, they become infectious and the whole tone of the place is lowered. But coupled with justifiable pride must be an ultimate humility; for it is from humility that all humanity stems. Indeed, the nice balance of pride and humility is the basis of good morale.

The administrator who despises staff negotiating machinery is foolishly shortsighted. Often negotiations are piffling in themselves; in fact, they are then acting as an emotional safety-valve. They are also a training in occupational democracy, and sometimes they may even be of real value in righting genuine wrongs. Their final use is as a means of dealing with the complaining psychopath; a curse inside any organisation. Once the complaints of the psychopath get into the official machine there is every hope of their being able to travel up and down for years without harming anyone.

ADMINISTRATORS AND DOCTORS

Perhaps the greatest difficulty which faces the hospital administrator is his relationship with the doctors. It is a subtle and difficult one. The medical man who decides to become a hospital administrator is, in this country at any rate, in a worse position than the layman. Other doctors tend to regard his decision as one dictated by lack of clinical skill, and they will dispute his administrative decisions simply because they resent the possibility that they may be based on medical knowledge. On the whole, therefore, I am in favour of the lay administrator; but it may sometimes happen that a medical man proves himself to be supremely competent in administration, and our system should be sufficiently flexible to make use of such exceptions to any general rule.

One of the great advances brought by the National Health Service has been the abolition of medical hierarchy in hospital as it was seen in most local-authority hospitals, and as it is still seen in some Service hospitals. The substitution of a number of parallel teams, units, or firms gives to the senior doctors complete clinical autonomy, without which, in my view, good medicine cannot be practised. The new liberty and equality take getting used to. The fraternity needed is not always forthcoming, and the need does sometimes arise for a measure of discipline, to correct either laziness or clinical failings on the medical side. I have no doubt that such discipline can only be a self-discipline applied by the medical profession itself.

The question is, how should it be applied? What is the best technique? The medical staff committee is a useful device, but only sometimes will its chairman feel that he has the necessary authority to administer a correction to his colleagues. Where his personality is such that he is able to do this, I have no doubt that he is the right ally for the lay administrator.

The Americans seem to have adopted a good system, whereby the chief of each department is known as a "chief of service." These chiefs of service form a medical board, and one of them is elected its president. The board meets weekly to perform an audit of service in the hospital, and any medical failures are investigated before the board and, if need be, correction is administered. The medical board is the police machine for the medical side of the hospital, and it looks as though it works effectively. It would be an interesting experiment to see such boards tried in a few English hospitals; save on the rarest occasions, it is not part of the job of the medical committee to investigate the failings of medical staff, yet healthy self-criticism inside each hospital might do a lot of good.

I am quite sure it is wrong to try to establish any other kind of supervising machinery for the doctors. Good medicine demands the occasional taking of risks, and those risks must be taken in the interest of the patient without regard to possible subsequent lay criticism. The doctor who is always looking over his shoulder at some other authority is certain to be a bad doctor.

If administrators are varied in their personalities, so too are the doctors. And doctors, like administrators, are subject to special occupational risks. Doctors may be brusque and rude at times; above all they may exhibit contempt for lay authorities. This is entirely healthy. Their job is to serve their patients, and not toady to committees or officialdom. The doctor who successfully squirms his way into the good graces of the lay authorities may be a poor servant of his patients. Long may the doctors continue to knock about all who are set in authority!

There are, however, other aspects of medical behaviour where improvement is eminently desirable. It might be expected that medicine would be a profession which broadened the mind; in fact, it often has the reverse effect. Partly this is due to the situation in which a doctor sees his patients; they want his help, and self-interest dictates deference and honesty. But partly it is due to the *high remuneration which doctors have commanded* for many years; even at the outset of their careers this is now the rule. This places them in a different position from the rest of society, where such high earnings are exceptional. Yet doctors tend to take their high cash rewards as a matter of course. So you will sometimes find that they regard themselves as a privileged community. High cash rewards certainly produce isolation. But privilege is to be earned and won by service, and each generation of doctors must earn and win it anew.

The way our doctors behave is, in part, determined by the way we treat them. The social contract of medicine is not a one-sided affair, and if we as patients accept rudeness, brusqueness, inadequate explanations of our troubles, and low standards of waiting-room accommodation, then we have only ourselves to blame if these continue.

Having criticised my own profession, perhaps I may be allowed to add that similar failings may be seen in administrators. Moreover, it is the job of the administrator to cope with such failings, whereas in medicine they are quite secondary to the performance of the job itself, the science and art of healing.

CENTRE AND PERIPHERY

One of the great jobs of this half-century is to establish the right relations between the centre and the periphery. We have to work out the right level at which policy decisions are to be made, and the right level at which to translate them into action.

In the administrative creation of a national service, there are two phases. The first is a process of centralisation, when the greatly varying local units are integrated and welded into potentially efficient local groups, and gross local defects are ironed out. The second process is one of decentralisation, when power is shed at the centre, so that only a broad planning function remains. There is no doubt that Parliament designed the National Health Service wisely in this respect; indeed the first circular of all (R.H.B./1) sets out a reasonable relation between the Ministry, the boards, and the management committees. The muddle which has followed is due to the activities of a small group of Civil Servants who are bogged down by their inexperience of practical work in hospitals or any other peripheral administration. The flood of circulars which they have produced proves this. *Mistakes are occurring continuously at the periphery*—and always will do so in any large service. A small proportion of these fortuitously reach the centre. They are there studied and analysed, and detailed administrative steps are worked out in vacuo for the prevention of similar errors. The result is a circular which bears only on the past. For in future it will be other and different errors, or similar errors in new circumstances, which will cause trouble.

The battle of the periphery against the centre will not be won until regional boards receive block grants, to spend as they will, subject only to the broadest general directions (including, however, minimum wage-rates and conditions). When regional boards have won their battle, it is every bit as important that they, in their turn, should give the fullest autonomy with block grants to management committees. Of course, the work of management committees *must be watched, and stimulated* from time to time. But it is the duty of the region again to lay down principles of work, leaving the details of execution to the periphery. Indeed devolution should be the rule down to the humblest employee. But it carries with it the necessity that everyone, *all the way down the scale*, should both feel responsible and be responsible for doing the job. And if devolution is to be combined with effective work, the *higher authority must be prepared* from time to time to pounce upon the lower, and to be pounced upon from above in turn. Such pouncings must become steadily rarer as one goes up the scale, or they will make nonsense of devolution.

To create a feeble administrative and executive body, give it 30 or more members, representing as many different interests, and no power over its own finances. With any luck, no action at all will result. Private enterprise has learned by bitter experience that the proper size for an executive committee of directors is from 5 to 7. I look forward, in the not too distant future, to regional boards and hospital management committees of this size,[1] with every decision definitive, no subcommittees, and the members paid a small directorial fee for their work. It is sometimes said that the payment of such fees makes the directors less willing to resign as a method of coercing the centre. I do not think this is so, since it is very rare to find unpaid nominated committee members who are ready to resign on specific issues. In any case, the threat of resignation is a poor weapon, save in exceptional circumstances.

The small board or committee not only simplifies administration, but keeps the administrator much more on his toes. In the multi-committee system the slacker can assist in the process of getting nothing done, by feeding potential decisions into committees, where they run up and down the line for months. With the single definitive committee, this is impossible.

SIZE OF COMMUNITIES

Another great job for this half-century is to find out the right size for different social groups. This is part of what I call "social architecture." There are certain basic material considerations, where the physical and the social scientist and the economist can make precise statements at the outset. In hospitals these include, for example, the turnover of cases of any *particular* kind necessary for the development of medical and nursing skills. Some material considerations, such as those of supply, are of secondary or even tertiary importance compared with human considerations. My personal internal experience is limited to some five former voluntary hospitals, three former municipal hospitals, and one Service hospital. I am fairly sure that too big a hospital of any kind is a mistake; here I include mental hospitals, mental-deficiency institutions, and chronic-sick hospitals. I put 600 beds *in one institution* as the maximum, and I am not sure that this is not too many; but I may be wrong.

It seems to me that the ultimate strength of any society is determined by the size of its peripheral units. If they become too big, there is a point at which spontaneous disruption takes place. If, on the other hand, they become too small, they lack the technical skills which follow from specialisation. Our job is to find the happy optimum, which may well be different for different types of community. Sometimes there will be a clash between the technical and the human considerations. Such clashes can almost always be resolved by getting the full facts on both sides. The more *detailed* the data, the more easily does the decision make itself. There is, however, often the need for an act of creative ingenuity in the solution of such difficulties; and in the final analysis, human considerations must always win.

---

[1] Taylor, S. *Lancet*, 1951, ii, 725.

GROWTH, REGRESSION, AND PROGRESS

Every society and community has its dynamic. Some folk think they can make the world stand still, but it is only they who remain motionless; around them there will always be advance or regression. In Canada, if one leaves a farm for a year or so, a forest of conifers springs up and engulfs all. One can only beat Nature by keeping at it. In administration it is the same thing. You can only beat the laziness, the sloth, the selfishness, and the sluttishness which is in all of us, by keeping at it. In small-scale private enterprise, if one lets things drift, the firm goes bust. In large-scale enterprise, public or private, it is possible to ride on the machine for years; but slowly the oil and petrol will be exhausted, the bearings will be worn, and one day you or someone else will find you are riding on a wreck.

It is the job of the administrator to make things tick, and to take command of the dynamic processes of a hospital. In any institution, there will be points of growth and points of regression, responses to increased or decreased need. Existing interests will fight the regression, for no-one likes to see his own department withering away. Yet a new discovery—for example, the new methods of treating venereal disease—may greatly reduce the needs, and facilities must be reduced correspondingly. Similarly, conservatism may struggle against desirable growth.

On the other hand, there are the people who want to empire-build for personal reasons. It is a high administrative skill to be able to distinguish the good man faced with a genuine need for expansion, from those who desire to build for the sake of self-importance.

It is vital never to confuse buildings with progress—a common fault with lay committees. I know of no more dreary sight than the empty hydrotherapy and physiotherapy rooms which decorate so many mental hospitals. Time and again the great work of medicine has been done in humble environments. Addison, Hodgkin, and Bright worked at Guy's in buildings which were old in their day. Yet they built a clinical tradition without equal. It was with home-made apparatus that the atom was first split at Cambridge, and the possibility of radioactive isotopes established. Whenever I see marble magnificence in hospital architecture, and excessive polish and tidiness, I at once suspect that I am looking at something second-rate. After all, the hospital is a noble institution, but it is an over-head on society, as indeed, is the whole of curative medicine. We must remember that and keep our activities and our demands in proportion.

In all administration the act of creation is one of great excitement. It should be a source of additional satisfaction when it is achieved with the smallest possible outlay of money, materials, and man-power. I venture to commend the little health centre which has been built by the Harlow Development Corporation, as an example of what can be done without great expenditure of capital.[2] In all new buildings be on guard against the grandiose. We must build efficiently and with beauty, but the grandiose is seldom either efficient or beautiful. I think it is unwise for any public authority to employ more than a very small nucleus of staff architects: the great bulk of its building should be entrusted to outside firms. Architecture is a creative art, and as a rule it flourishes best in an environment of freedom and risk. Stereotyped dullness in public architecture is usually associated with the salaried architect, though the converse is not necessarily true.

The creative act is not necessarily expensive. It need not be so, and, when the health service is fully deployed, creative acts will often save money. At this particular point in the growth of the health service, when big capital developments are impossible, it is vitally important that all administrators should be trying out new ideas. It does not matter how small the scale of these experiments; it is the spirit of experiment, of improvisation, of adventure, that is important. The psychiatric day hospital is one experiment which commends itself to me as a possible means of saving hospital beds. The Mothers' and Babies' Hospital at Newcastle upon Tyne seems another useful experiment. The experiments which have been carried out in the field of geriatrics since the Appointed Day are most exciting. Less happy, I feel, are some efforts at creating rehabilitation centres, where one has a suspicion that industrial neurotics may be holidaying, rather than recovering.

I commend also the process of marsupialisation—or opening up to the outside what is at present inside. As applied to hospitals this means open access for general practitioners to pathology and X-ray departments, and pushing the specialist services out to the periphery. I have in mind a small laboratory in charge of a technician, or a small gymnasium in charge of a masseuse, serving perhaps fifteen or twenty general practitioners in an outlying area.

Do not be put off by the growls of the vested interests in your hospitals. There is no need to wait until health centres are built for we can create an atmosphere of coöperation not by creating new committees, but by coöperating in our daily work. Above all, do not wait for the Ministry of Health cumbrously to formulate its mind. Get moving with your own experiments and innovations, for it is at the periphery, where patient and service and doctor meet, that the real work is done. It is at the periphery that the real opportunities for advance now exist.

A POSTSCRIPT ON TRADITION

Every institution has its pattern of behaviour; if the institution survives for several generations, the pattern crystallises into a tradition. A tradition of snobbery, of rigidity, of self-satisfaction can be stultifying in the extreme. On the other hand, a tradition of open-mindedness, of adaptability, of humanity, and of energetic achievement can be a constant stimulus to better performance. In Britain we are fortunate in having a number of institutions, in greatly differing fields of endeavour, with traditions of superlative performance. Whatever the initial motives may have been, with the passage of time, the superlative performance becomes an end in itself. Though standards may fluctuate at times, at their worst these institutions are still among the world's best. Among such institutions and their products I number certain ancient schools, colleges and hospitals, the Royal Navy, the *Times* and the *Manchester Guardian*, in more specialised fields *Nature* and the *Lancet*, the productions of our two older university presses, the branded Scotch whiskys, the Bristol sherries, and Stilton and Wensleydale cheeses. To these continuing superlatively excellent human achievements our modern age makes its select additions. The Rolls Royce motor-car, the de Havilland aeroplane, and the B.B.C. are worthy of admission to our Pantheon. I hope that one day our National Health Service, and in particular our hospital service, may have proved itself as a member of this select band.

The essence of such achievement is unvarying quality of service. All who come to us should receive the best that mankind anywhere has to offer. This does not mean frills or luxury, but skilled, dutiful, and courteous service, free from all red tape and restriction, so given that there is no loss of self-respect to either giver or receiver. In conception the National Health Service is a precise expression of the Christian ethic. Our task is now to match the conception with performance, in which task the hospital administrator has a vital part to play.

Special Articles

UNITS FOR THE TREATMENT OF BURNS

THE proper care of burns requires special hospital arrangements, as the work of the Birmingham Burns Unit has demonstrated. The Ministry of Health [1] have now asked regional boards and boards of governors of hospitals to consider together the establishment of burns units in each region, and to give the problem priority. The units, they say, are needed not only to provide an ordinary peace-time service, and to disseminate knowledge of newer methods of treatment, but to serve as training centres in this particular aspect of Civil Defence.

In any one year, it is estimated, 17,500 patients with burns and scalds need admission to hospital in England and Wales—that is 1 case in 2500 population. About two-thirds of these cases are the result of accidents in the home. (The Ministry note that with proper safeguards these home accidents could probably be reduced by half.) If the average stay in hospital is reckoned to be 35 days, each region will need at least one bed per 25,000 population; and in fact it is generally believed that the average stay would be longer than this. A unit of twenty to thirty beds in each region is suggested; even where there is one unit already, as in the Birmingham region, the Minister favours the establishment of a further unit. Industrial and heavily populated areas, where large numbers of burns may be expected, should be chosen, and regional boards and boards of governors are asked to consider together the hospitals in which units can best be developed. Existing units will serve as a guide when units are being set up.

THE QUARTERS

The Ministry base their proposals for accommodation on the recommendations set out by Dr. Leonard Colebrook, F.R.S., in his book,[2] though they point out that, with the present building restrictions, his full design cannot be attempted. It should be possible to adapt existing buildings or to establish a unit in huts, and the capital cost need not then be large. Wards will be needed for men, women, and children. In order to check the spread of infection, not less than a quarter of the total number of beds should be in single-bed cells, ventilated as in an ordinary isolation hospital cubicle. The remaining beds, the Ministry say, can be in open small wards or subdivided large wards. There should also be one or more single-bed rooms measuring 10 ft. by 12–15 ft., for the treatment of shocked patients during the first 24–48 hours. In addition one, or preferably two, rooms, measuring 15 × 16 ft. or at the very least 14 × 12 ft., are needed for the dressing of burns.

The Ministry insist that the dressing-rooms should be air-conditioned. It will be remembered that Colebrook emphasised the importance of this, to prevent the spread of infection. Infection, of course, is not only a common cause of death from burning, but delays healing and the opportunity for skin grafting. The system chosen should provide 12 air changes an hour, and the air-temperature should be thermostatically controlled at 70–75°F. The circular says that draughts must be avoided, but does not specifically recommend the air-locks proposed by Colebrook.

The cost of air-conditioning such a room is surprisingly low: thus a suitable system for a room measuring 15 × 16 × 13 ft. (with louvred inlet, filter of the throw-away type, heater battery, fan, and ducting to high-level damper-controlled fresh-air inlets, and low-level extract fan discharging to the external air) is only about £200 to instal, plus the cost of any necessary supporting arrangement for the plant. The maintenance cost is between 5*d.* and 6*d.* an hour. The Ministry regard it as desirable, but less important, to provide similar ventilation for the shock rooms. The extra cost of extending the plant and ducting to serve more than one room would be £50–100.

THE TEAM

The Ministry insist that the unit must be under the direction of a small team specially designated for the purpose. This, they suggest, should consist of one or two surgeons (general, traumatic, and possibly plastic) who, in addition to their other duties, are willing to engage part-time in this work. They think it unlikely that any surgeon would agree to spend all his time on the treatment of burns. This has not been the experience of the Birmingham unit; and it will be remembered that Colebrook believes it to be important to place the unit under the charge of a director, supported by a full-time team. He also thinks it essential that new cases should be seen and assessed within a few moments of their arrival at hospital by a senior and experienced member of the team.

Besides the surgeons, the team suggested by the Ministry would consist of a whole-time registrar or senior registrar, seconded from the regular staff for 6–12 months, who could be relieved or assisted from time to time by other registrars in the hospital; and one house-surgeon or senior house-officer who could be relieved or assisted by the other residents. Full pathological services, the Ministry note, will of course be necessary, and there should be close liaison with a plastic unit.

This arrangement has the drawback that the doctor on the spot will never have had the long experience of burn cases which is necessary if the best results are to be achieved; and the picture as a whole falls far short of the team trained for the job envisaged by Colebrook. But it might in time lead to that, if a sufficient number of keen men become interested in this difficult subject.

As the Ministry point out, the medical profession has only recently become fully convinced of the need to provide specially for the treatment of burns; and a burns unit in every region may therefore serve as a valuable demonstration. In modern warfare there would probably be large numbers of burns among the population; and improved methods of treating peace-time burns would provide valuable experience in such an emergency. They therefore think that surgeons, senior registrars, and registrars should be seconded for 2–3 months to the regional burns unit from other hospitals. But the boards will need to meet any capital costs this year, for establishing burns units, from the capital sums already allocated to them, and this year's maintenance costs must be met from funds allocated for revenue expenditure.

NEW COLOURS FOR GAS CYLINDERS

THE Medical Defence Union, the Association of Anæsthetists, and the British Oxygen Company, acting under the ægis of the British Standards Institution, have been studying the prevention of accidents caused by giving the wrong anæsthetic gas. Dr. Robert Forbes, secretary of the Medical Defence Union, informs us that action will shortly be taken to put their recommendations into effect.

The possibility of using a non-interchangeable valve, which would make it extremely difficult to give the wrong gas, has been considered, but no decision has yet been reached. But changes in the colour of gas cylinders have been agreed to on an international basis.

The colours that have been given to cylinders in this country conflict with those used for similar gases in other countries, and serious errors and fatal accidents have resulted. To remove this danger a list of standard colours, names, and symbols for medical gas cylinders has been prepared. This involves changing the colours of most of the cylinders at present in use in the United Kingdom.

---

[1] Circular R.H.B.(52)69, B.G.(52)66.

[2] A New Approach to the Treatment of Burns and Scalds. London, 1950; see *Lancet*, 1952, i, 908.

Suppliers of cylinders will make the necessary changes, and they are arranging to collect and repaint cylinders as quickly as possible. Close coöperation between suppliers and users will be necessary to reduce the change-over time to a minimum and to avoid the dangers of having in use for even a short time cylinders of two different colours containing the same gas.

One particular gas will be dealt with at a time: the first cylinders to be altered will be those containing nitrous oxide, which are at present painted black. The colour will be changed to French blue, and repainting will begin on Aug. 1, 1952. Suppliers should be told at once when empty cylinders are ready for collection, and any nitrous-oxide cylinders that are unlikely to become empty in the immediate future should also be returned.

When all the nitrous-oxide cylinders have been changed, the repainting of other cylinders will begin. Hospitals will be told about this by the Ministry of Health, and further particulars will be given by the suppliers.

During and for some time after the transitional stage, a gas must be identified by reading the name or the chemical symbol on the cylinder, and not by colour alone.

A new colour chart will be issued to hospitals. Those who would like copies now may obtain them from the British Standards Institution, 24, Victoria Street, London, S.W.1.

Hospital authorities are being asked to display the following notice in all places where gas cylinders are handled or gas is used:

> "Starting on Aug. 1, 1952, changes will take place in the colouring of medical gas cylinders; to identify the gas, reliance must be placed primarily on the name of the gas or the symbol stencilled on the cylinder and not on the colour of the cylinder."

Copies of the notice should be given to every doctor, dentist, nurse, and midwife engaged in the hospital, and to all porters and other persons who handle gas cylinders.

Every medical gas cylinder arriving in the hospital, and every cylinder already in stock, should be marked with a red tie-on tally bearing in heavy black type the words:

> *DANGER:* COLOURS ARE BEING CHANGED. READ THE LABEL AND CHECK THE SYMBOL AND NAME OF GAS.

Hospital authorities should see that frequent inspections are made to ensure that the tallies are in position on all cylinders.

Anyone about to use an anæsthetic machine should first verify the couplings of the apparatus. Safety can be achieved only by observing the following rules: (1) Read the name of the gas or the symbol on the cylinder. (2) Check the coupling of the anæsthetic apparatus. (3) Test the gas for identity at the delivery end.

WORK OF THE KING'S FUND

H.R.H. the DUKE OF GLOUCESTER, presiding at the annual meeting of King Edward's Hospital Fund for London on June 25, announced that the Queen has consented to become patron of the Fund.

The main lines of the present phase of the Fund's work were, he said, becoming fairly clearly defined. By visiting the hospitals and making grants for a great variety of purposes it had been able to lend a helping hand in many different ways. ("The list includes, I am glad to say, a number of grants to mental hospitals, mostly for the improvement of the recreational facilities.") If and when times became easier it might be practicable to look at rather larger projects. Meanwhile the Fund was glad to be able to expand its activities in other directions to meet what were generally felt among the hospitals to be real and pressing needs.

"The plans made four or five years ago are now taking effect; last year saw the opening of the Hospital Administrative Staff College at Palace Court, the School of Hospital Catering at St. Pancras, and the conclusion of an extensive special survey made by the Convalescent Homes Committee. We are now about to submit to the Ministry of Health the conclusions of our investigation into the possibility of cost accounting in hospitals. In this current year, too, the foundations are being laid for a course designed to bring a fresh approach to the work of the hospital matron, taking account of recent changes in outlook on the technique of management."

Two more of the Fund's homes for the aged sick had been opened recently, one at Ealing and one at Sydenham, and another would be opened at Blackheath the same afternoon by the Duchess of Gloucester. Work was in progress on other homes.

SIR EDWARD PEACOCK, the treasurer, said that the Fund's total receipts during the year had come to over half a million pounds. It was very satisfactory that the receipts from legacies should continue to be so well maintained. Grants to hospitals and convalescent homes reached a total of £170,000, and over £132,000 was expended on setting up and administering special services. Sir ERNEST POOLEY, chairman of the management committee, said that no-one could read the annual report without realising the enormous importance of voluntary effort not only for hospitals but for the country generally. Mr. MALCOLM MCCORQUODALE, M.P., speaking as chairman of the Hospital Administrative Staff College, reported that in the first complete year 112 administrative officers, many of senior rank, had followed one or other of the courses. The students of the first full training course had just completed four months' study at the college and were now about to enter on a period of hospital practice under supervision. They would return later to the college for further study and would, after that, again be placed in suitable hospitals to complete their practical training. It had always been the intention to use the college as a centre for the study of hospital problems as well as for the provision of courses of instruction, and already there was a group actively engaged on the question of "making the best use of hospital beds."

Mr. J. W. BOWEN, chairman of the North-East Regional Hospital Board, endorsed to the full the passage in the report: "It seems clear that with the continuance of straitened circumstances hospitals will increasingly find that the relatively small sums that can be made available by the Fund are nevertheless often the means of achieving ends disproportionate to their size."

THE DURHAM DISPUTE

REPRESENTATIVES of Durham County Council and of the Joint Emergency Committee of the Professions agreed on June 26 to ask the Minister of Labour and National Service to appoint a board of arbitration with the following terms of reference:

> "It being accepted by the parties that the professional employees of the county council represented by the Joint Emergency Committee of the Professions—namely, dentists, doctors, professional engineers, midwives, nurses, and teachers—should not as a condition of employment be required to belong to a trade union or professional organisation, the board are asked to determine:
>
> (i) whether the present regulations of the council governing the making of applications for extended sick pay are in conflict with the principle of voluntary membership of a trade union or professional organisations and should therefore be withdrawn; or
>
> (ii) whether the regulations are made in the present exercise of the discretion vested in the council in the granting of extended sick pay and are not in conflict with the principle of voluntary membership of a trade union or professional organisation."

Both the county council and the Joint Emergency Committee of the Professions undertook to accept and implement any award of the board of arbitration.

The teachers' organisations decided to withdraw forthwith the notices of resignation which had been handed in by them on behalf of their members, and the county council decided to suspend immediately the operation of the regulation which had given rise to the dispute. Further, the professions agreed to take all other necessary action to close the dispute.

The Minister has since appointed Sir John Forster Q.C., to be chairman and Prof. D. T. Jack and Mr. J. W. Bowen to be members of the board of arbitration, which will meet in London on July 15.

Sir John Forster is president of the Industrial Court. Professor Jack holds the chair of economics at Durham University. Mr. Bowen is a former chairman of the London County Council.

In England Now

A Running Commentary by Peripatetic Correspondents

AN interest in history is no doubt one of the signs of middle-age; I must own that when I had rooms in the medieval court of Corpus Christi College, Cambridge, I neither knew nor cared whether it was the first court built in an English university. All the same, when I joined in the college's sexcentenary celebrations last week, and looked up at the lovely Saxon church of St. Bene't, or Benedict, I realised that the beauty of the place and its setting had left its mark on me for life, though I did not appreciate it at the time. From this court, thirty years ago, we medical students set out to hear lectures by, among others, two future presidents of the Royal Society—Gowland Hopkins and E. D. Adrian. Perhaps we did not realise that we were getting a university education as well as a medical one. I was lucky enough to have a practising physician as my supervisor of physiology; when I met him at the celebrations he repeated an old argument of his that the Cambridge undergraduate's education is often too medical and too good. Everyone agrees that it is too medical—but who dares take the first step to make it less so? It is too good when a man has only to remember what he is told, and need never think for himself to pass his exams.

One of Corpus's most famous sons made his name by thinking for himself—about blood-pressure. Many rank Stephen Hales's discovery with Harvey's; but it was in the versatility of Hales's mind that his real genius lay—he constructed an instrument to slow down the motion of the heavenly bodies; he produced a leaden cast of the bronchial tree; he invented an instrument to whip cream and another to ventilate prisons; he measured the pressure of the rising sap; and, as every Corpus man should know, he timed the growth of bone before John Hunter was born. Many of us are still following Stephen Hales's example in testing "unsatisfactory conjectures" and trying to make history as well as study it.

* * *

It was noteworthy that Potter, in his recent radio talk on Doctorship, did not mention its newest branch, Non-Smokership, which has developed out of all recognition since the discussions in these columns 18 months ago. Lifemen who, like myself, had already given up smoking years ago because we could not *afford* it, can now make a virtue of necessity. As our plutocratic friend proffers his gold cigarette case we can achieve wonders with a mere raising of an eyebrow, a look of surprise, and a more-than-usually emphatic "No, *thank* you." Observing the effect of such an approach is one of the keen pleasures of true Doctorship. The victim may show slight but unmistakable signs of truculence; or he may make an uneasy attempt to laugh it off, remarking, "I shot my bolt long ago, Old Boy." The correct counter-ploy here is, "I'm sorry you take that attitude, Old Chap." As X. Odoreida has pointed out, the strength of this riposte lies in the words "Old Ch[illegible] ith the protagonist's "Old Boy"; if [illegible] this phrase will imply that the Lifeman is a generation wiser and more self-disciplined than his companion.

The serious practice of Non-Smokership offers as much scope as any branch of Doctorship—indeed, it covers almost the whole vast field of Lifemanship. One word of warning, it can be carried too far. As Potter himself would say: *One Must Know When to Stop.*

* * *

A geneticist friend of ours finds himself in an interesting position. From his youth he has been aware that in the matter of vomiting he is not as other men. Not for him the cough, the retch, the beads of sweat, the partial tearing of the abdominal muscles. All he has to do is switch in some hypothalamic overdrive and *up* it all comes. His wife, it seems, is cast in more fragile clay, and vomits in a routine manner. They have two children, both as a rule possessed of cast-iron stomachs. Nevertheless, the boy has succumbed to various infections, and our friend has been interested to observe on these occasions that his vomiting follows the maternal pattern. It is with the girl, however, that the future rests. In earliest infancy she was a good regurgitator, but for the last two years nothing would induce her to vomit. The other day she obliged on the dining-room sofa, and our friend was delighted to recognise at once a kindred spirit. He is now chattering happily about fourth-generation siblings, and he has already reserved a little black square for himself at the head of the family tree to be published in THE LANCET of A.D. 2052.

* * *

It was as a schoolboy that I first learnt of the traditional inability of doctors to express themselves without using long technical terms. An example was the medical witness who said his patient had "sustained a severe contusion of the integument under the left orbit, causing extensive abrasions of the cuticle, with local extravasation of blood and ecchymosis into the subcuticular tissue"; to which the learned judge remarked "You mean he had a black eye?" For fifty years (and God knows how long before that) this monstrosity of pathological hyperbole has been employed to flagellate us for our stupidity.

Whenever a book on forensic medicine or an article or lecture on medical evidence is published, one looks with confidence for this venerable example of supposedly customary practice. I have always regarded the doctor who was originally responsible as a lineal descendant of Mrs. Harris—the choice perfection of the phraseology smells too much of the lamp. But since it is just possible that it really issued from the lips of a colleague with more fluency and love of accuracy than sense of proportion, I always write to ask for chapter and verse. So far there has been no response; nor do I anticipate one to my latest inquiry on its reappearance only last week. It will live for ever—unless someone can invent another example which is equally striking and slightly more probable.

* * *

After a couple of stillbirths and a miscarriage or two, Mrs. D at last had a daughter, born by cæsarean section. As she left the hospital sister expressed the hope that she would be coming back some day. Mrs. D thought this over but concluded that she didn't know: "After all I've been through," she said, "I'll be a bit precautious."

* * *

I took it hard when a patient of mine told me that the osteopath she works for as secretary had given her sulphacetamide drops for her sore eye. Not that I objected to his treatment, which was successful, or to his interference, which was kind. My point was that this osteopath had used the orthodox weapons he pretends to reject. If he had manipulated her cervical spine he would at least have been consistent. Heretics must have the courage of their heresy if they want other people to take them seriously.

* * *

Looking for a cheap hotel in a north Italian town last summer I came across one that looked just what I wanted—clean, at least relatively so, and simple. In a ground-floor window there was a large placard advertising the virtues of the restaurant in four languages. At the top the announcement was given in Italian: "*Pránza al prezo fisso. Cucina del casa.*" Next came its equivalent in German, and below that in French: "*Repas à prix fixe. Cuisine familiale.*" Last came the English version: "*Meal at fixed price. Familiar cook.*"

* * *

Conversation before operation:

"When you were off work for 18 months, did you have a pain?"—"Yes, Doctor."

"Where?"—"My doctor said it was round my heart."

"I see. Show me just where it was."—"Round my heart, Doctor."

"Yes, but point with this finger to where the pain was worst."—"I can't do that, Doctor."

"Why not?"—"I don't know where my heart is."

Letters to the Editor

RESISTANT STAPHYLOCOCCI

SIR,—The article by Dr. Clarke and her colleagues (June 7) is one of several recent reports on the increasing number of drug-resistant staphylococci in hospital infections. We are apt to forget how much more heroic some branches of surgery have become under the protection of antibiotics, and it would be a tragedy if we allowed the present trend to continue.

The following points regarding hospital staphylococcal infection are important:

1. Staphylococci far exceed all other pathogens as the cause of secondary infection.

2. Wards which have patients with chronic staphylococcal suppuration build up a reservoir of drug-resistant staphylococci.

3. The most important mode of spread is: contaminated dressings → floor → blankets → fresh wounds. It is true that many of the staff may be transient or even permanent carriers: but masking and a no-touch technique in wound dressing reduces the nose → finger → wound spread, and in my opinion droplet spread is of minor importance with respect to staphylococci.

4. The measures taken to prevent cross-infection in many hospitals appear to be concerned almost exclusively with respiratory and streptococcal infection. Adequate bed-spacing, face masks, and bowls of 'Dettol' have no doubt contributed to the eclipse of the streptococcus. But when a staphylococcal infection is treated in the ward, contaminated particles from the dressing are commonly swept from one end of the ward to the other, alighting on bed-clothes from which they are thrown up to descend on fresh wounds when these in turn are exposed.

5. This mode of spread may have little importance in acute surgical wards, but is of very great importance in orthopædic wards. The sum of misery and frustration brought about by the ubiquitous staphylococcus is still very high. Amyloid disease still arises from unnecessarily infected tuberculous sinuses; spinal grafts are still extruded, screws are loosened, and tendons destroyed; chronic osteomyelitis still occurs, and is still one of the most distressing of all diseases.

As we are not controlling the staphylococcus by antibiotic therapy, we must consider how to stop the spread of this organism in chronic surgical wards. The measures I would suggest are:

(*a*) Separation of infected from non-infected patients. Separate wards may be impossible, but there is no need to put a patient with a tuberculous abscess requiring aspiration in a bed adjacent to one with a discharging osteomyelitis.

(*b*) Dressing-rooms for all dressings and examinations. No peeping at wounds in the open ward.

(*c*) No dry sweeping. A vacuum-cleaner suitable for hospital wards is an urgent necessity.

(*d*) Careful supervision of the disposal of infected plasters and dressings in the theatre as well as in the ward.

(*e*) A patient in an orthopædic ward, discharging staphylococci that are resistant to the antibiotics in common use, should be isolated.

Royal National Orthopædic Hospital, Stanmore, Middlesex.
CHARLES H. LACK
Pathologist.

PERIPHERAL FACIAL PALSY

SIR,—Mr. Terence Cawthorne's article (June 20) on peripheral facial palsy and his observations on its pathology in an earlier communication[1] provide a valuable contribution to our knowledge of this condition.

Particularly interesting is the analysis of the ætiology in 129 cases in which the lesion was intratemporal, and in which the facial nerve was exposed at the upper level of the lesion. One infers that no case of Bell's palsy was met with in which a lesion could be demonstrated in the tympanic segment or upper vertical segment (as he has named them), whereas 53 cases were found in the lower vertical segment.

Does Bell's palsy ever involve the facial nerve as high as the geniculate ganglion? Mr. Cawthorne says that between the geniculate ganglion and the level of the chorda tympani there is no guide as to the site of the lesion except the cause. Does he consider the stapedius reflex of any value in localisation? If the patient complains of hyperacusis as well as facial palsy and taste disturbances, would this constitute a dependable indication that the level of the lesion is above the level of the nerve to the stapedius? It would seem theoretically that the presence of hyperacusis should provide a guide for lesions suprachordal but infrageniculate (provided lacrimation is normal).

I have at the moment in general practice a schoolmaster, aged 40, who experienced a feeling of tightness not amounting to pain in the left ear and overnight developed complete left peripheral facial palsy. In addition he complained of painfully loud hearing on the same side, particularly painful when using the telephone. There was smarting of both eyes but not one more than the other. He had a feeling in the left side of his tongue anteriorly as though it had been scalded by hot fluid. These complaints developed concurrently with the palsy.

The palsy is very obvious, there being pronounced dropping of the angle of the mouth, inability to close the eye, and loss of forehead furrows on the affected side.

Examination of the ears shows nothing abnormal. Weber test normal. Rinne's test positive on each side, but air-conduction lasts longer on the left than on the right side and some sounds are painful. Hearing is normal for conversation and whisper. The tympanic membrane is normal: there are no herpes spots. Taste tests are inconclusive, all the front of the tongue being unreliable. Blood-pressure and central nervous system normal. Wassermann reaction not yet known.

In such a case is one entitled to conclude that the lesion of Bell's palsy extends from the stylomastoid foramen to the geniculate ganglion, and that if decompression had to be carried out the lesion would be found in the tympanic part of the nerve or above?

All authorities agree that it is impossible to give a reliable prognosis in the first week or two after the onset of a complete Bell's palsy even with the help of electromyography, &c. Has Mr. Cawthorne, from his survey of 325 cases, gained any hint as to prognosis based on an assessment of the clinical features in the early days of the palsy? Thus is there any suggestion that a severe case such as I have described carries a worse prognosis as regards recovery of full function than a case of complete peripheral facial palsy without evident involvement of the chorda tympani, stapedius, and lacrimal gland, or with involvement of the chorda tympani only?

It seems unsatisfactory indeed that the only indication for the operation of decompression is the absence of clinical or electric evidence of returning function a month or more after the onset of the palsy. One would imagine that meanwhile irreparable harm would have overtaken the nerve.

Sheffield.
E. C. ATKINSON.

⁂ We have shown this letter to Mr. Cawthorne whose reply follows.—ED. L.

SIR,—The term Bell's palsy implies a lesion of the facial nerve-trunk in the lowest part of the vertical segment just above the stylomastoid foramen. Since first recognising at operation the characteristic appearance of the nerve-trunk in this situation, it has been noted in all but 4 of the cases of facial palsy submitted to decompression. The swelling and discoloration of the nerve-trunk in Bell's palsy has never been seen to extend higher than 1 cm. above the stylomastoid foramen. It remains to be seen whether in severe cases the swelling extends higher than this; and if so whether it is the same disease. Only by looking and seeing can this be found out.

That the lesion is in the lowest part of the intratemporal part of the nerve is suggested by the effect on taste; for in many cases taste is unaffected, although the chorda tympani nerve joins the facial less than 5 mm. above the foramen. Loss of taste is often experienced in cases which subsequently recover spontaneously; and very occasionally when it is unaffected complete recovery does not take place.

---

[1] *Lancet*, 1951, ii, 593.

The stapedius reflex is disappointing as a localising sign; for the undue sensitivity to loud sounds which might be expected to follow paralysis of this muscle rarely happens, even when the nerve to stapedius is affected. This may be because its work is taken over by the other intratympanic muscle, the tensor tympani, which also contracts in response to loud sounds, and which receives its innervation from the fifth cranial nerve.

The prognosis in Bell's palsy depends upon the extent of the paralysis and the ability of the nerve to transmit an electrical stimulus. Of 45 cases in which the paralysis was incomplete, 44 had shown improvement within two months. On the other hand, of 107 cases in which the paralysis was complete, 58 showed no sign of recovery after two months. Of 92 cases in which the nerve retained its ability to conduct an electrical stimulus, only 1 failed to show any sign of recovery within two months; whilst of 60 cases in which the response was lost only 3 showed any sign of recovery within two months. Though severe pain and loss of taste often accompany the more serious lesions, I have noted both these phenomena in incomplete paralysis where spontaneous recovery is the rule.

I wish that I could give more definite answers to Dr. Atkinson's interesting and pertinent questions; and I feel, as I think he does, that early decompression offers the best chance of preventing irreversible damage to the nerve.

At present the most that can be said in the earliest stages is that where the paralysis is complete the chances of total spontaneous recovery are evenly balanced with the prospect of eventual partial recovery or none at all. Confirmation, by electrical tests, of the severity of the lesion must wait for two weeks, during which time, as Dr. Atkinson says, irreparable harm may have been done. I sincerely hope that it will not be long before we can tell within a day in which cases decompression is needed.

London, W.1. TERENCE CAWTHORNE.

SUCCINYLCHOLINE

SIR,—I hasten to thank Dr. Bourne and his colleagues for their excellent and significant contribution, published in your issue of June 21.

There is, however, one procedure described by them that should be acted upon only with caution and full knowledge of the mechanisms involved. After suggesting that, at the end of an operation in which *d*-tubocurarine chloride or gallamine triethiodide has been given to provide relaxation, succinylcholine may be used when the abdomen is to be closed, in order to avoid the further use of the longer-acting agents, they proceed to recommend the administration of neostigmine "even in a full 5 mg. dose" "when the succinylcholine has worn off, if there remains any doubt whether the patient has sufficiently recovered from the curare or gallamine." This procedure is safe provided that one can be absolutely sure *that all the succinylcholine* has been hydrolysed. It is, however, my suspicion that after large doses, or repeated small doses, of succinylcholine the return of *some* respiration does not necessarily mean complete removal of all the drug; for we have observed and recorded a case which has, in fact, returned to a state of apnœa following a dose of neostigmine, and the cessation of respiration lasted for a not inconsiderable time.

There is another sequence of drugs in which the unwary may be inclined to indulge and which may lead, I believe, to serious results. It is conceivable that there may be circumstances in which, at the end of an operation, after the administration of anæsthesia which includes *d*-tubocurarine chloride or gallamine triethiodide and neostigmine, the surgeon may for some reason decide to reopen the abdomen—for example (although this may seem far-fetched with modern methods of checking) to find a missing swab. The anæsthetist may then be tempted to produce temporary relaxation with succinylcholine. I have, for quite a different reason, given this sequence—*d*-tubocurarine chloride, succinylcholine, atropine, neostigmine, succinylcholine—and although the last dose of a succinylcholine was, in fact, only 25 mg., there resulted a most alarming bradycardia (pulse-rate in the region of 30 per minute) followed by vomiting of what appeared to be recently secreted stomach contents. This picture did not appear until immediately after the administration of the succinylcholine. Conceivably the bradycardia was unrelated to the succinylcholine but a possible mechanism would be an intense inhibition of tissue cholinesterase due to the combined action of neostigmine and succinylcholine. The previously administered dose of atropine (1·3 mg.) was evidently insufficient to prevent this.

I believe that there may be a place for the administration of more than one relaxant agent to a patient in order to attain a desired result. This polypharmacy, however, must be practised only with full realisation of the interaction of these agents and of the relation they bear to other drugs which may be administered; otherwise there will be danger of the anæsthetist losing that complete control of the situation which is one of the great advantages resulting from the advent of these valuable agents.

Department of Anæsthesia,
University of Liverpool. T. CECIL GRAY.

WHAT SHOULD THE NURSE BE TAUGHT?

SIR,—I read Miss Humphreys's letter (May 24) on nurse-cadets with considerable sympathy, but I must challenge her statement that "this is the considered opinion of my colleagues in the teaching profession."

The Association of Head Mistresses have discussed nursing-cadet schemes on many occasions, not only among themselves, but also with the Association of Hospital Matrons. While sympathising with the difficulties that such schemes are designed to solve, both in hospitals and for girls leaving school at 15, it is the considered opinion of the Association of Head Mistresses that they are not the best solution of these difficulties and, indeed, that they create additional problems for both hospitals and girls.

AGNES CATNACH
Past-president of the Association
London S.W.18. of Head Mistresses.

COTTON SUTURES

SIR,—I read with interest the letter from Dr. Patrick (June 7).

We have always understood that the primary *factors* in surgical sutures should be uniformity of *gauging*, maximum tensile strength, and absence of tissue *irritants*. Whilst we agree that economy should be exercised in the use of all materials in hospitals, it *is surprising* that, when such high standards are demanded from the recognised manufacturers of suture materials, the surgical profession are prepared to purchase reels of cotton, &c., from the ordinary haberdasher.

Cotton thread seems to have little following in this country; but we should be quite prepared to investigate the possibilities of supplying a similar material manufactured under strict control, ensuring reliable gauge and tensile strength. You will appreciate that firms marketing ordinary cotton and linen thread for domestic and industrial purposes are not obliged to announce any changes in their manufacturing procedures which might involve change of dye, filling, &c.; and a change of this kind might have serious complications for patients into whom the thread was implanted.

From information that we have received—albeit somewhat vague—as to the cost of major operations—expenditure on suture materials seems to represent little more than 1½%. Thus the saving in buying "uncontrolled" suture materials would be a fraction of 1% of the cost of the operation and thus an infinitesimal percentage of the total cost of the hospital services.

Ethicon Suture Laboratories Ltd.,
Edinburgh.

W. J. WARD
Product Manager.

MONILIASIS

SIR,—Your annotation (June 21) accompanying two reports of moniliasis draws attention to this condition following treatment with antibiotics. You suggest that, before starting treatment, precautionary measures should be taken: "First, before starting therapy with aureomycin, chloramphenicol, or terramycin, it is wise to ascertain, whenever possible, the bacteriology of the condition (where it is desirable to start treatment before the bacteriological report is known, penicillin or sulphonamides can be used in the first instance)."

Stuart[1] and Hulse[2] both reported serious infections of the bovine udder with yeasts of the candida species following treatment of the udder with penicillin. It might be questioned, therefore, whether penicillin is much safer in this respect than the other antibiotics.

Ministry of Agriculture and

SUDDEN DEATH IN INFANCY

SIR,—Your leading article last week rightly stresses the changing outlook on the cause of sudden and unexpected death in infancy, and mentions a number of current views on the probable causes. While you confine yourself largely to the type of case that comes before the coroner, the same problem is present in many of the deaths that occur in hospital.

Excluding cases of gross congenital deformity and of diseases that occur throughout life, such as meningitis, we know extremely little of pathological processes in children. In such cases we are commonly hindered by attempting to interpret gross necropsy findings in terms of adult pathology. You write: "At necropsy the thoracic viscera were congested and often covered with petechial hæmorrhages. These findings suggest asphyxia, but . . . the clinical picture was that of severe respiratory infection." Such petechial hæmorrhages are so common in infancy and occur in such diverse conditions that in my opinion they do not indicate asphyxia or necessarily even any respiratory disorder.

The cause of death in these infants dying suddenly will not be known to us until we know considerably more of the functional pathology of infancy—such as factors promoting pulmonary œdema or bronchial secretion.

A point that is often overlooked in cases of "sudden death" is that questioning of the parents privately and at leisure reveals that very few of the children were in fact "perfectly well when they went to bed and found dead in the morning"; and a history obtained by an enlightened social worker, such as a children's hospital almoner, is frequently found to be quite different from that obtained under the stress of the coroner's court. The term "unexpected death" describes these cases, rather than "sudden death."

While interchange of ideas would be extremely useful, at our present state of knowledge more will probably be learned by a few people doing very detailed investigations in different centres than by a coördinated investigation such as you suggest; for this type of investigation is only likely to produce large figures based on current pathological concepts.

ANATOMICAL NOMENCLATURE

SIR,—At the International Congress of Anatomists, held at Oxford in the summer of 1950, it was resolved to set up a committee, comprising three members from each of the countries (or groups of countries) represented, to make recommendations to the congress to be held in 1955 in France for the establishment of an agreed international anatomical nomenclature.

Hitherto there has not been an *agreed* international anatomical nomenclature. The B.N.A. (1895), despite the fact that it has been gradually adopted by most countries, was essentially the work of a small committee of exceptionally able German anatomists, and the fact that one British and one Italian anatomist were coöpted during its preparation did not make the B.N.A. an agreed international nomenclature. In 1933 the Anatomical Society of Great Britain and Ireland approved the revision of the B.N.A. carried out by British anatomists with the intention of bringing it up to date, and this revision has been in use in the anatomy departments of universities and medical schools in this country for nearly twenty years. The corresponding German society (Deutsche Anatomische Gesellschaft), working quite independently, published its own revision of the B.N.A. in 1936. Since then advances in knowledge, particularly in the section of neurology, have made it desirable for the whole position to be reviewed with the authority attaching to an international committee of anatomists.

With the sympathetic and material support of UNESCO and its appropriate branch, the Council for the Coördination of International Congresses of Medical Sciences, it proved possible to hold a meeting in London of one duly accredited representative from each country (or group of countries) concerned.

This meeting was held in the week May 26–31, 1952, when representatives were present from France (representing Belgian and French-speaking Swiss anatomists), Germany (representing Austrian and German-speaking Swiss anatomists), Great Britain (representing British, Irish, and Commonwealth anatomists), Holland, Italy, Scandinavia, Spain and Portugal (including the Spanish and Portuguese-speaking countries of South America), and the U.S.A. An invitation had been issued to the anatomists of the U.S.S.R. but no representative attended.

The principal object was to determine whether the proposal to attempt to establish an agreed international anatomical nomenclature at the present time was in fact practicable, and the matters discussed were, to a very large extent, matters of principle. Throughout the six sessions there was an atmosphere of cordiality and friendship which was not only encouraging but expressed itself in a willingness to compromise, whenever compromise could be considered reasonable and justifiable. As a result the committee came to the conclusion that the establishment of an agreed international anatomical nomenclature was practicable and it was decided to proceed therewith.

As a first step it was agreed unanimously that the B.N.A. (1895) should form the basis for an agreed international anatomical nomenclature and that the changes to be effected in it should be restricted as far as possible to those considered essential. The principles which had been adopted in the B.N.A. were fully discussed and, with a number of minor modifications, were unanimously adopted. Further, it was unanimously agreed that each country should be at liberty to translate the official term, which would be in Latin, into its own vernacular for teaching purposes, if it desired to do so, but the committee was very strongly of the opinion that in scientific publications, in anatomical or other medical journals, it was most desirable that the official Latin terms should be used—especially in the titles—to avoid ambiguity or uncertainty.

The detailed work will be carried out by a series of subcommittees and it was agreed to make a special effort to submit a report to the International Congress of Anatomists to be held in France in 1955.

While the committee felt that the revision of anatomical nomenclature was properly the responsibility of anatomists, they were well aware that it was most important to obtain the sympathetic coöperation of all who are actively concerned with the teaching of medical students in any branches of medical science, for it would patently be absurd to lay down for anatomists that each structure in the body should be designated by one term only, if no attempt were made to persuade physiologists, pathologists, clinicians, and others concerned, to use the same terms. It is, therefore, hoped that those who are interested in this matter will communicate their views to me, and I will gladly undertake to put them before the appropriate committee.

In an endeavour to make known as widely as possible that this revision of the B.N.A. will be an agreed international anatomical nomenclature in actual fact, each member of the committee has undertaken to make a similar communication to this in the responsible medical journal, or journals, in his own country and to forward to me such communications as he may receive.

Anatomists are most anxious to avoid antagonising any of their colleagues and they earnestly seek their coöperation both now and in the future. The B.N.A. (1895) has been gradually adopted in this country, and the aim of the committee is to restrict changes to be effected in it to the minimum, while recognising that in some respects, and especially in the central nervous system, the B.N.A. is outdated. It is apparent that such changes as it may prove necessary to introduce will take time to become absorbed into general medical terminology: but such terms as "dorsal vertebrae, Poupart's ligament, musculospiral nerve, internal lateral ligament of the knee-joint" have in the space of forty years almost entirely been replaced in this country by the terms "thoracic vertebrae, inguinal ligament, radial nerve, and medial ligament of the knee-joint" respectively.

Guy's Hospital, London, S.E.1. T. B. JOHNSTON.

INSULIN HYPOGLYCÆMIA AND EOSINOPHILIA

SIR,—Dr. Shattock and Mrs. Micklem (June 21) describe an eosinophilia after hypoglycæmic treatment in mental patients. Over twenty years ago I described eosinocytosis (perhaps a better word) from insulin injections without any hypoglycæmia.[1] I ascribed this to local reactions to an injected foreign substance. No doubt insulin is purer now and provokes less local reactions. But this local factor should be considered and ruled out by controls before eosinophil changes are ascribed to hypoglycæmia and reactions thereto in cortical and other hormone glands.

King's College Hospital, London. R. D. LAWRENCE.

SICKLE-CELL ANOMALY IN GREECE

SIR,—In answer to Dr. Caminopetros's letter (June 14) I should like to make the following remarks.

I insist that the bone lesions in Cooley's anæmia are not specific to that disease but can also be found, in lesser degree, in other anæmias. I believe, today as in the past, *that there is probably an ætiological relation* between malaria and Cooley's anæmia. The nature of this I do not know.

Dr. Caminopetros writes that, together with Dr. Roumanis, he found several patients with "the typical mongoloid facies of Cooley's anæmia" in the villages of Petromagoula and Scripou. We have not seen one. Moreover, using Singer's method for testing the alkali resistance of hæmoglobin our clinic has examined[2] the patients with sickle-cell anæmia in these villages and found percentages of resistant hæmoglobin between 5 and 19—values which fall within the limits reported by Singer in Negroes with sickle-cell anæmia. The values in patients with Cooley's anæmia have been found to be so much higher that this test can be used in the differential diagnosis between sickle-cell anæmia and Cooley's anæmia.

We disagree fundamentally with the ideas of Dr. Caminopetros on sickle-cell morphology.

THE DANCKWERTS AWARD

SIR,—I do not suppose I am the only elderly G.P. who has suffered loss in two wars and then of private practice, and so has of late found hard the struggle to make ends meet. To us the Danckwerts award has been as welcome as it was unforeseen, giving hope of some relief from anxiety, and the prospect of being again able to obtain the little luxuries for so long beyond our reach. Our thanks are due to those whose efforts have brought about this most happy consummation.

London, W.C.1. PRACTITIONER.

SHUNTING IN THE HUMAN KIDNEY

SIR,—The letter from Dr. Solymoss and Dr. Molnar in your issue of March 15, in connection with our article,[1] is very stimulating. We wish to clarify certain points which are raised there.

To study the vascular pattern of the kidney we have followed the histological technique described by Pickworth[2] who appears not to have based his method on Lepehne's[3] work. American workers[4] have called the technique the Lepehne-Pickworth method and not simply the Lepehne reaction or benzidine reaction, while elsewhere[5] it has been accepted as Pickworth's stain. We feel that "Pickworth's stain for blood-vessels" does itself imply the benzidine reaction as developed by Pickworth, whereas simple "Lepehne" or "benzidine" reaction may leave one guessing *about the technique followed—all the more so since at least* one other modification has been described.[6]

We regret that Solymoss's paper[7] escaped our attention. This was partly due to the fact that there was no mention of shunting or corticomedullary diversion or intrarenal redistribution of blood in its title, which had suggested to us rather a case-note relating anuria with cortical ischæmia. Franklin[8] has also cited this paper as providing evidence of correlation between anuria in abnormal pregnancy and cortical pallor.

Dr. Solymoss's article was based on a single case of eclampsia. The suggested engorgement of the vasa recta cannot be clearly appreciated owing to absence of a control picture. The exact vascular channels through which the cortical blood is diverted have not been defined. The vasa recta are said to be derived "from efferent vessels of juxtamedullary glomeruli"; but no such glomerulus can be made out in the photomicrograph, nor is it described in the text. If direct anatomical demonstration of the "Trueta phenomenon" (as *Dr. Solymoss and Dr. Molnar call it*) simply means demonstration of cortical ischæmia with medullary congestion, then we suggest that Maegraith and Findlay[9] were the first to do this from the plain macroscopic appearance of the cut surface of the kidney in blackwater fever, even *before* the experimental works of Trueta and his co-workers.[10] We believe that clear anatomical demonstration of shunting in the human kidney requires histological demonstration of cortical ischæmia and of the exact alternative channels through which the blood is diverted. *Certainly Dr. Solymoss*[7] has clearly demonstrated histologically cortical ischæmia *in the human kidney with the* vascular stain, but the exact pathways of diversion have not been defined. Trueta[11] has himself described and depicted most clearly the prominent juxtamedullary efferent vessels breaking up into pencils of vasa recta, but no cortical ischæmia was demonstrable in his cases.

CONTROLLED HYPOTENSION DURING SURGICAL OPERATIONS

Sir,—Since my paper on this subject (June 28, p. 1286) was submitted for publication, estimations of cerebral venous oxygen content have been made, at arterial pressures of 60 mm. Hg and less, on blood samples taken during neurosurgical procedures. These have shown that cerebral vasodilatation very nearly compensates for the fall in arterial pressure, so that under the conditions used by us cerebral anoxia does not occur.

TREATMENT OF RHEUMATOID ARTHRITIS WITH BUTAZOLIDINE

Sir,—Just over a year ago 'Irgapyrin' (Geigy) appeared in this country. This substance contains amidopyrine and butazolidine in equal parts, 12½ grains of each in one intramuscular injection of 5 ml. In some cases of rheumatoid arthritis and osteo-arthritis little effect was obtained, but most patients' symptoms were relieved, and this relief was occasionally striking. It seemed to Currie[12] that the relief obtained was greater than could be expected from the amidopyrine content alone. He therefore tried the effect of the solvent, 1 : 2-diphenyl-3 : 5-dioxo-4-n-butylpyrazolidine (G 13871 or butazolidine; also known in the United States as phenylbutazone), and we understand that you are publishing his results this week.

At Dr. Currie's suggestion we began investigating the effects of this substance in the rheumatism unit of this hospital at the end of last year. 16 patients have had courses of butazolidine lasting five to fifteen days; 2 received 800 mg. daily by mouth in divided doses, and the remainder had 1 g. (5 ml.) daily by intramuscular injection. Our first supplies came with control ampoules, and we were unaware which substance was control and which butazolidine. All patients received both substances one after the other in varying order. In treating the first 4 patients we soon recognised the active substance, for it relieved pain in all 4, though there was no reduction in swelling as measured in the fingers by jewellers' rings (Hart and Clark[13]). The other 12 patients gave similar results; in most cases reduction in pain and consequent improvement in function were seen, but no objective changes were produced except in the 3 cases described below. Relief of pain usually wore off within a week of stopping the drug.

Case 1.—Mrs. A, aged 50, had early generalised rheumatoid arthritis of only four months' standing. Her swollen fingers did not improve after full salicylate therapy, control substance, or butazolidine, each given for five days. A sixteen-day course of adrenocorticotropic hormone (A.C.T.H.) by six-hourly injection, 60 mg. daily gradually decreasing to 28 mg. daily, reduced finger swelling by 11 ring sizes. The usual rebound followed the withdrawal of the drug, and finger swelling increased by 30 ring sizes in the next fortnight. Butazolidine was then given intramuscularly for nine days, during which time the fingers diminished by 6 sizes, and in the next five days by a further 19 sizes. Five months later a ten-day course of butazolidine following a control period produced no reduction at all. In retrospect it is likely that the apparent improvement was in fact a spontaneous one following an A.C.T.H.-withdrawal exacerbation.

Case 2.—Mr. B, aged 40, had had generalised rheumatoid arthritis for three years. Swelling of the proximal interphalangeal joints diminished by 10 ring sizes after a nine-day course of butazolidine, but relapse followed when the drug was stopped.

Case 3.—Mr. C, aged 40, had had rheumatoid arthritis for just over a year. After intramuscular butazolidine for ten days, his fingers were reduced by 6 sizes, and in the next four days by a further 4 sizes. Within eleven days of stopping treatment the swelling was as great as before, the fingers having increased by 10 sizes. This rebound, seen in some cases only, is of interest because it suggests that there may occasionally be a true reduction in swelling.

In the other 13 patients no significant reduction in finger swelling was seen when compared with the effect of the control injections. Subjective improvement though usual was not invariable: 3 patients obtained no relief from the short courses given. One further case is worthy of note.

A man, aged 32, had had recurrent swelling and stiffness of various joints for many months. These bouts had become very frequent, and pain, swelling, and stiffness in one or more joints were to be seen every day. On oral butazolidine (2 g. six-hourly for eleven days) the swelling disappeared, but recurred on the second day after withdrawing the drug.

It seems that in this case butazolidine prevented the occurrence of swelling. Our impression is that it is more effective in relieving the pain of rheumatoid arthritis and osteo-arthritis than in other conditions. Several patients with other types of pain found it inferior to the usual analgesics, and Dr. Currie makes the same point.

No toxic effects (such as have been reported in the United States after prolonged therapy), gastro-intestinal upsets, purpura, œdema, or drug rashes were seen. The toxic effects that have been described usually followed oral dosage.

In the United States experience with much larger series has been entirely similar to our own: the drug has excellent analgesic properties whether given by injection or by mouth in long or short courses, but little or no evidence of true antirheumatoid activity has been found, and sedimentation-rates have been unchanged.

The bulk of available evidence suggests that we have in butazolidine a drug which definitely lessens the pain of rheumatoid arthritis but which has no constant antirheumatic effect. It deserves further study.

SURGERY OF PEPTIC ULCER

Sir,—I was interested to read the comments of Sir Heneage Ogilvie (May 31) and of Mr. Patey (June 7) on this subject.

When ulcers have been large or highly placed on the lesser curve I have, for some years, "timed" the operation of gastrectomy, by awaiting complete or almost complete healing as shown by X-ray examination. I have seldom treated these patients medically in hospital and seldom kept them away from work; healing has taken place according to the natural history of the disease. Even the largest ulcers seem to heal with time alone, and the time of healing is probably not very much changed by intensive treatment. Perhaps the time of healing of an ulcer, from the moment the physician or surgeon first sees the case, is related more to the stage of its development in relation to its natural history than to any treatment used.

In cases of duodenal ulceration X-ray examination is often not reliable as evidence of healing, since in so many there is gross deformity of the duodenal cap. Freedom from symptoms and absence of tenderness are not, in my experience, sure signs that the duodenal wall is healthy enough for suture. I regard prepyloric closure with mucosal ablation as so safe that I seldom attempt to "time" the operation. In a series of some 350 cases of gastrectomy for duodenal ulceration, done by my registrars and myself in two hospitals, there has been no case of stump leakage since we first used the Bancroft

13. Hart, F. D., Clark, C. J. M. *Lancet*, 1951, i, 775.

operation in 1947; this operation has been done in some 40 of these cases.

Very rarely the exclusion operation may be the method of choice. Otherwise it should be mentioned only to be condemned, for it has no advantage over the Bancroft operation and is usually followed by a second operation to excise the retained antrum. I did, in a small series of cases, use this operation before I came to know how very safe is prepyloric closure with ablation. I did not follow it by a later operation to excise the antrum; for I believed that, if this retained segment of stomach caused jejunal ulceration, then its excision would cure that ulceration. Oddly these few cases have not yet developed this condition, although it is now some years since the operations were done.

Sir Heneage is right when he states that the operation of prepyloric closure with mucosal ablation is "slightly untidy." The patient is, however, asleep when the operation is done: he lives only to know its worth.

London, W.1. HAROLD BURGE.

SIR,—An article from the pen of Sir Heneage Ogilvie is invariably refreshing and inspiring. His address on the First Part of the Duodenum is fully deserving of the tribute paid him by Mr. David Patey.

Much as I respect Mr. Patey's surgical views, I am surprised at his strong advocacy of milk—particularly its administration by the drip method—in the treatment of acutely inflamed duodenal ulcer. The giving of milk from "on high" by the drip method certainly anchors the patient to bed, and often exercises a peculiar fascination for him. Some of our cases have become veritable milk-drip addicts, offering occasional difficulty in weaning!

At best, however, milk is a weak antacid, and some of my colleagues and I have found that patients derive just as much benefit from the rest in bed and a mixture of the type advocated by Dr. Arthur Douthwaite as a preliminary to operation.[1] One of the disadvantages of milk is that the patient tends to put on so much weight, and recently a surgical colleague found to his disgust that he had to deal with the unrepentant ulcer of a patient who had gained three stone after an extended course of this treatment.

Incidentally it is remarkable how many doctors there are, afflicted with duodenal ulcer, who are content to have medical treatment for their relapses, rather than face the prospect of a gastrectomy.

London, W.1. MICHAEL J. SMYTH.

APPOINTMENT SYSTEMS IN HOSPITAL OUTPATIENT DEPARTMENTS

SIR,—In the article (May 31) by Brigadier Welch and Mr. Bailey two important factors appear to have been overlooked: (1) patients who make an appointment and fail to arrive; and (2) patients who make an appointment which is not recorded. At a large teaching hospital I attended this year, three appointments had been made for 10 o'clock and no record of them could be found on the consultant's appointment-sheet.

London, S.W.11. AUBREY H. CARTER.

AUTOGENOUS VACCINE

SIR,—I have a patient under my care in hospital for whom I asked the appropriate laboratory to make a vaccine. I was met with a refusal to do so on the ground that the organisms discovered were not likely to make a useful vaccine. These organisms were a streptococcus of somewhat indeterminate character and the patient's own brand of *Micrococcus catarrhalis*. He suffers from bronchitis and asthma which have proved very resistant to ordinary remedies. Can you, Sir, tell me where I can learn how the potentialities of any particular autogenous vaccine can be discovered otherwise than by its clinical use?

Sevenoaks, Kent. GORDON WARD.

HOSPITAL COSTING

SIR,—Your leading article on this subject (June 21) pointed out some deficiencies of the present method of hospital costing. In particular, you questioned the credentials of the practice of counting five outpatient attendances as the costing equivalent of one inpatient day. I suggest that a source of greater error is the failure to adopt a standard unit to measure equivalent amounts of work done in the various departments. Reference to note (ii) on page 6 of the report *Hospital Costing Returns*[1] shows that "one outpatient attendance" is not, for the purpose of costing, the same as "one patient attending the Out-Patient Dept. once." Other items such as "treatments or examinations in physiotherapy, pathological, radiological and similar departments" are also included.

This report refers to the financial year ending March 31, 1951, and the statistics on which the costing is based were obtained mainly from various returns of the Ministry of Health for the year ending Dec. 31, 1950. At that time there was considerable confusion both at the Ministry and in the hospitals as to what constituted a "unit" in pathological and similar departments. As the Ministry had not been able to produce satisfactory definitions to cover these points, there was great diversity in interpretation which led to the same examinations and treatments being valued at different rates in different hospitals. This invalidates the costing figures based on these statistics, since an elementary rule of comparative costing is to compare "like with like." The instructions on how to compile these costing figures issued by the Ministry (R.H.B.[50]66) to boards and management committees should have been included in full in the report since the merits of any statistical report can only be judged on the reliability of the source data; and not everyone who may wish to use this report will have easy access to official files.

Later, in an attempt to clarify the situation, the Minister of Health issued a circular (R.H.B.[51]59) from which we learn that "for the purpose of costing" the following services are rated as equivalent to *one outpatient attendance*: (1) X-ray examinations enumerated on the basis of the "requests" received from clinicians, irrespective of the number of films used or the time taken to complete the examination; (2) a single pathological specimen of blood, urine, cerebrospinal fluid, &c., regardless of the number or quality of the tests performed on it; (3) a treatment in the physiotherapy department, simultaneous treatments to be counted as one but group treatments (e.g., remedial gymnastic classes) to be counted as *one for each patient attending*; (4) even more surprisingly, a necropsy is counted as one outpatient attendance, but histological or other special examinations should be counted as one for each organ even where more than one block or specimen is examined from the same organ. In view of this heterogeneous collection of so-called "units" you will no doubt agree that the exact ratio employed to equate these to one inpatient day is hardly of practical importance. It is well to note that the costing statistics for the financial year ending March 31, 1952, will be based on figures compiled in accordance with these instructions. Whether or not the Ministry will have revised its definitions of costing units in time for the 1952/53 financial report is as yet unknown.

There is a tendency among the members of the medical profession to regard all questions relating to costing as the concern of the administrative side of the hospital service. But in fact it is the concern of us all; for in these days of financial stringency the whole policy of administration of the health service may depend on costing statistics. At no time in the foreseeable future will money be so plentiful that costing will be unnecessary, so that whether or not we regard costing as desirable it is certainly inevitable. If the medical profession realistically accepts the necessity of comparative costing then it would be to its advantage to ensure that the figures bear at least some relation to the truth.

MALARIA IN EX-SERVICEMEN

SIR,—We are engaged in a war in which our troops are fighting in malarious theatres—Korea and Malaya—whilst others are stationed in more peaceful malarious places, such as West Africa. The incidence of malaria in all these theatres is within reasonable bounds and on the whole is surprisingly low. Various preventive measures are used but considerable emphasis is laid on 'Paludrine' as a prophylactic, the experiences with which have been satisfactory.

Paludrine, in common with other drugs, may only act as a suppressant of benign tertian malaria, and clinical attacks may occur when it is discontinued. Benign tertian malaria is the predominant malaria of Korea, and it is therefore to be expected that a number of attacks of malaria will occur amongst soldiers who have returned from that theatre. The numbers recorded are low, the total in this country last year averaging only 16 per month; and, the disease being benign, there is no immediate grave risk to the individual. It is, however, inevitable that some of these soldiers suffer relapses after demobilisation which may occur quite quickly after their return from Korea, and it has been brought to my notice that a number of cases amongst demobilised men have only been diagnosed after prolonged examination and treatment for other diseases, neither the doctor nor the patient having considered the possibility of malaria.

A strongly worded warning is given to soldiers on their return of the possibility of a relapse, but in the cases referred to this mechanism has failed for one reason or another to put men on their guard. If practitioners meet cases of acute febrile illness amongst recently demobilised men they should bear the possibility of a malarial relapse in mind, seeking early confirmation of the possibility either by referring the patient to an appropriate hospital or by arranging for the rapid examination of blood films.

Ross Institute of Tropical
Hygiene, Keppel Street,
London, W.C.1.

G. MACDONALD
Hon. Consultant
in Malariology
to the War Office.

SIR,—During the past few weeks we have had under our care several cases of benign tertian malaria in men returned from military service in Korea. In each instance the history has been that the patient has taken regular prophylactic paludrine whilst overseas and has remained in good health. The paludrine has been stopped during the voyage home, the patient has returned to civilian life, and some weeks or months later he has developed a tertian fever which, with one exception, has not been suspected as being due to malaria until it has continued for upwards of three weeks, by which time the patient has become considerably debilitated and anæmic. The exception referred to was a regular soldier who had had a previous experience of malaria and came to us on his own initiative on the fourth day of his illness.

This long delay between the onset of symptoms and the recognition of the nature of the disease magnifies what should be a trivial episode of ill health into quite a serious illness. Much time, money, and anxiety can be saved if it is remembered that benign tertian malaria is a likely explanation of a fever occurring within twelve months of a visit to Korea.

Public Health

Economy in Local Government

THE Ministry of Housing and Local Government has sent to local authorities a circular reinforcing the call by the Chancellor of the Exchequer, in his budget speech, for "economy in the sphere of local government as well as national government."

With regard to urban water-supply and sewerage where work is proposed on grounds of public health, an appendix to the circular states:

> It must be established that the scheme is not merely desirable but is essential on public health grounds. The fact that existing conditions are unsatisfactory in some respects may not mean that they are necessarily a danger to health. Examples of schemes which will be considered on this count are those for replacing works or machinery that are in danger of breakdown with consequent failures of supply; work for obviating pollution of water-supplies that may give rise to disease; sewerage schemes designed to relieve flooding inside dwelling houses; and the improvement or replacement of sewage works that are overloaded or obsolescent to an extent that may give rise to conditions that will affect the health of people in the areas concerned. Any claim that works are necessary on grounds of public health must be supported by a report from the Medical Officer of Health on the nature and extent of the danger.

Statistics for 1950

The civil tables volume [1] of the Registrar-General's report for 1950 shows that during the year the birth-rate in England and Wales was 15·8 per 1000 population; this was a decrease of 0·9 per 1000 from the previous year's rate. Stillbirths amounted to 23 per 1000 total live and still births. Of the legitimate maternities 40·2% were to mothers with no surviving previous children, 32·2% to mothers with 1 surviving child, and 14·7% to mothers with 2 surviving children.

The First Quarter in Scotland

The Registrar-General for Scotland [2] reports that in the quarter ended March 31 this year the birth-rate was 18 per 1000 population, which was 0·8 below the rate for the corresponding quarter of 1951. Stillbirths amounted to 29 per 1000 live and still births. The death-rate was 14·5 per 1000 population—3·3 less than in the first quarter of 1951. The infant-mortality rate—38 per 1000 live births—was 8 below that for the corresponding quarter of 1951. The neonatal death-rate was 23 per 1000 live births, which was 2 below that for the corresponding quarter in 1951. The death-rate from tuberculosis was 47 (respiratory 41) per 100,000 population, compared with 58 (respiratory 51) in the corresponding quarter of 1951.

Housing in Edinburgh

An interesting light is cast on housing progress in Edinburgh by the first detailed report [3] that has emerged from last year's Census of Scotland.

In the twenty years since the previous census in 1931, the number of occupied private houses has risen from 105,702 to 134,038—an increase of 26·8%, compared with an increase in the private-household population of only 5·6%. On April 8, 1951, the average number of persons for each house was 3·29, compared with 3·95 in 1931. In 1931 and 1951 the population was distributed as follows:

No. of persons per room	*1931* (%)	*1951* (%)
Not more than 2	72·1	89·0
More than 2 but not more than 3	17·4	8·8
More than 3 but not more than 4	6·9	1·6
More than 4	3·6	0·6

The number of one-roomed houses has fallen from 7123 (6·7%) to 5173 (3·9%). Two-roomed houses have fallen from 33,591 (31·8%) to 31,255 (23·3%). Three-roomed

1. The Registrar-General's Review of England and Wales for the Year 1950. Tables, part 2, civil. H.M. Stationery Office. Pp. 176. 5*s.*
2. Quarterly Return of the Registrar-General, Scotland: Births Deaths; and Marriages Registered in the Quarter ended March 31, 1952. H.M. Stationery Office. Pp. 30. 2*s.* 6*d.*
3. Report of the Fifteenth Census of Scotland: vol. 1, part 1. H.M. Stationery Office. 7*s.* 6*d.*

houses have increased from 26,934 (25·5%) to 44,475 (33·2%), four-roomed houses from 15,687 (14·8%) to 28,293 (21·1%), and five-roomed houses from 8114 (7·7%) to 11,537 (8·6%).

With regard to conveniences, the figures for households, in percentages, are as follows:

	Exclusive use	*Shared use*	*None*
	%	%	%
Kitchen sink	90·3	8·9	0·8
Piped water-supply ..	89·5	10·2	0·3
Cooking stove or range ..	88·3	6·9	4·7
Water-closet	80·3	19·5	0·2
Fixed bath	60·4	7·4	32·3

59·7% of households had exclusive use of all five conveniences; and of the total of 141,472 households 39 had no conveniences at all.

Of the 134,038 occupied private houses, 5874 (4·4%) were occupied by *two or more households*. Of these 5874 houses, 4809 (81·9%) had two households, 660 (11·2%) three households, and 405 (6·9%) four or more households.

Parliament

Hypnotism Bill

In the House of Commons on June 27 Mr. **Somerville Hastings** moved the third reading of the Hypnotism Bill, which as amended in Standing Committee prohibits absolutely demonstrations of stage hypnotism on persons under 21 years of age. Demonstration is permissible on those over 21 in certain circumstances. Where places in which demonstrations are intended to take place are licensed for music and dancing the demonstrations are permissible provided that the authority concerned is agreeable.

The Bill was read the third time and passed.

Burns in the Home

On June 27 the House of Commons gave a third reading to the Heating Appliances (Fireguards) Bill, which aims at the reduction of two classes of burn accidents in the home: those caused to children, and those caused by clothing catching in an exposed element or flame. Mr. **Denys Bullard**, in moving the third reading, paid a special tribute to the work of Dr. and Mrs. Leonard Colebrook and to the many other doctors who had aided him.

Royal Assent

In the House of Lords on June 26 the Royal Assent was given by Commission to the Corneal Grafting Bill, the Family Allowances and National Insurance Bill, and the Cremation Bill.

Working Party's Report

The Parliamentary Labour Party has issued the following statement concerning the report of the Working Party[1] which was set up to consider the distribution of the Danckwerts award and the future distribution of the general practitioners' central pool of remuneration:

"The Parliamentary Labour Party does not propose to oppose the Danckwerts findings. However, having carefully studied the report of the working party on the future distribution of the central pool, the Parliamentary Labour Party affirms that a most valuable opportunity has been missed to better the general-practitioner service to the public and to improve the standard of doctoring throughout the country. Moreover, the report fails adequately to improve the position of the young and poorer paid doctors having small lists of patients, and gives the greatest increase of payment to those who are already receiving higher rates of remuneration. Its proposals for the encouragement of group practice are grossly inadequate.

"When this subject is debated in the House, the viewpoint of the Parliamentary Labour Party will be elaborated and constructive modifications will be proposed."

QUESTION TIME

Medical Evidence and National Insurance Claims

Replying to Mr. C. C. **Poole**, Mr. **Osbert Peake**, Minister of National Insurance, said there were no statistics to show in how many cases in the five months ending May, 1952 insurance officers had refused to accept the medical evidence of incapacity supplied in support of a claim.

Mr. **Poole**: What further evidence would the Ministry require in support of a claim, apart from that of the medical practitioner who examined the patient, and on what authority do the officers of the Ministry refuse a claim when such evidence is forthcoming? Mr. **Peake**: In my opinion it would be quite wrong to tie down the insurance officer and compel him in every case to accept a medical certificate without question.

Hospital Staff Economies

Replying to Major **Guy Lloyd**, Mr. **Iain Macleod**, Minister of Health, said that precise figures were not available, but it was estimated that a saving of 5% of establishments so far reviewed would result from the reports of teams investigating administrative and clerical hospital staffs.

Prescription Charges

Replying to Mr. **Richard Ewart**, Mr. **Macleod** said that he was not prepared to exempt from the prescription charge chronic sick patients who required dangerous drugs which were dispensed weekly. When such drugs were prescribed on a weekly basis, they were not usually required for periods so long as to make the ordinary provision for relief of financial *hardship inappropriate*.

Replying to Dr. A. D. D. **Broughton**, Mr. **Macleod** said that the approximate cost of a National Health Service prescription in England and Wales in 1948, 1949, and 1950, accounted for by the payment of the dispensing fee and the cost of the container and of drugs, medicines, and dressings, was as follows:

Period	Av. cost of dispensing fee per prescription	Cost of container allowance per prescription	Av. ingredient cost of drugs and appliances per prescription
1948: July–December	1*s.* 1*d.*	2½*d.*	11*d.*
1949	1*s.* 0*d.*	2*d.*	1*s.* 2¼*d.*
1950	1*s.* 0½*d.*	1¾*d.*	1*s.* 5¾*d.*

Figures for 1951 were not yet available.

Vaccination against Tuberculosis

Mr. **Anthony Greenwood** *asked the Minister of Health* how many local authorities had schemes in active operation for B.C.G. vaccination, and how many persons had been so vaccinated.—Mr. **Macleod** replied: 143 local health authorities have had proposals approved authorising the use of B.C.G. vaccine. Approximately 32,000 persons were vaccinated under approved schemes between October, 1949, and Dec. 31, 1951.

Mr. **Greenwood**, asked what was the present state of medical research in this country in regard to vaccination with the vole bacillus vaccine.—Mr. **Macleod** replied: A large-scale trial with this vaccine is being carried out under the auspices of the Tuberculosis Vaccine Trials Committee of the Medical Research Council.

Hospital Outpatients

Replying to Major **Lloyd**, Mr. **Macleod** said that the total numbers of new outpatients who attended hospital consultative clinics in England and Wales in each of the years 1949–51 inclusive were as follows: 1949, 6,147,825; 1950, 6,193,156; and 1951, 6,298,746.

Appointments

Couch, A. H. C., M.D. Lond., M.R.C.P., D.C.H.: asst. chest physician, Ipswich Chest Clinic.

Fisher, J. D., M.C., M.R.C.S.: appointed factory doctor, West Nottingham district.

Goddard, D. L. H., M.D. Lond., M.R.C.P.: consultant chest physican and deputy medical superintendent, St. Wulstan's Hospital, Malvern.

Marshall, A. G., M.D. Camb.: part-time consultant pathologist, Wolverhampton group of hospitals.

Parish, Christopher, M.B. Manc., B.SC., F.R.C.S.: consultant Regional Hospital Board thoracic surgeon, East Anglian hospitals and the United Cambridge Hospitals.

Rutter, L. D., M.B. Manc.: appointed factory doctor, Yarmouth district, Norfolk.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

---

[1] See *Lancet*, 1951, i, 1147, 1155.

Notes and News

NATIONAL INSURANCE CHANGES

An order made by the Minister of National Insurance fixes the days on which the increased insurance benefits and family allowances will come into force. Sickness, unemployment, industrial-injury, and widow's benefits will be paid at the new rates from July 24; the family and guardian's allowances from Sept 2; and the retirement pensions (including widow's retirement pension) from Sept. 29. The higher contribution rates will operate from Oct. 6. The total weekly National Insurance contribution for an employed man over 18 will then be 10*s*., of which he will pay 5*s*. 5*d*. himself.

The Minister has also increased the time allowed for claiming some industrial injury benefits and for obtaining payment of a benefit after it has been awarded. The time allowed for claiming disablement benefit is increased from 1 month to 3 months. Injury benefit must still be claimed within 21 days, but this limit will be relaxed to some extent for hospital inpatients. Payment of a benefit already awarded may now be made up to 6 months after the award, and in the case of disablement and death gratuities the time-limit has been discarded altogether. These changes applied from July 1.

The Ministry has prepared a leaflet, which will shortly be issued to general practitioners, giving details about the medical certificates required for insurance purposes. The amended regulations, which came into force on May 26, make a number of changes in the rules governing certification. Only three types of certificate will be in use instead of five. A copy of the regulations will be sent to practitioners as soon as possible. The leaflet describes the use of the new certificates, but the old certificates will continue to be used until supplies of the new ones have been distributed.

ACTION UNDER THE CORNEAL GRAFTING ACT

The Ministry of Health suggests that those who wish to offer their eyes for use after their death, under the terms of the Corneal Grafting Act, should take the following steps: (1) make a written statement of their wish that their eyes should be used for therapeutic purposes after their death; (2) give this to their family or anyone else with whom they live; (3) give a copy also to any executors appointed to carry out their will; and (4) inform the authorities of any hospital which they may enter as an inpatient of their wish that their eyes should be used after death for this purpose.

University of Oxford

On June 25 the honorary degree of D.LITT. was conferred on William Somerset Maugham, M.R.C.S.

The degree of D.M. was conferred on E. M. Poulton and A. N. Cammock on June 7 and not on March 11 as we stated previously.

University of London

Mr. P. H. Mitchiner has been reappointed deputy vice-chancellor for the year 1952–53. Dr. C. F. Harris has been elected dean of the faculty of medicine for the period 1952–54.

Dr. J. R. Napier, lecturer in anatomy at St. Thomas's Hospital Medical School, has been appointed to the university readership in anatomy tenable at the Royal Free Hospital School of Medicine, from Oct. 1 this year.

University of Durham

The following degrees were conferred on June 27 and 28:

M.D.—W. A. Brown, L. W. Carstairs, W. P. Haigh, M. M. Martin, Alexander Russell, C. B. S. Schofield, J. N. Walton, P. D. G. V. Whittingham.

M.B., B.S.—P. R. Bachrich, A. L. Bass, A. R. Bird, D. H. Blake, D. W. Braithwaite, *James Brotherton, Ann K. Brough, William Brough, *D. D. Brown, A. T. Burdon, D. W. Cammock, W. A. Colling, L. P. Coulson, Margaret L. Coulson, Betty E. Cowling, Alan Coxon, A. J. Coyer, Kenneth Davison, Doreen L. P. Dias, Wilfrid Dickson, Raymond Dingley, Donald Elliott, J. S. Etherington, A. D. W. Farmer, P. G. Fawcett, W. T. Fothergill, June E. Heslop, James Ivory, Frank Johnson, G. S. Jeans, *Elizabeth Jennings, M. H. Kemp, P. E. Kilby, J. C. King, Elsa Little, H. A. McClelland, J. F. S. T. McClory, Peter McElhatton, John McKinlay, I. R. Macleod, C. F. R. Mallett, T. J. Mallinson, R. A. Middleton, D. G. Millar, Betty M. Moody, G. H. E. L. Morpeth, *J. H. Morrison, John Mulroy, R. W. Newmark, N. C. C. Nielsen, S. J. O'Donnell, T. W. Parkinson, I. B. Porteous, John Richardson, *Elizabeth R. M. Rowell, Patricia J. Saunders, Kirt Schapira, Thomas Scratcherd, Arnold Shaw, R. H. Shields, L. K. Simango, A. J. Smith, K. D. Stephenson, Mary E. A. Still, *G. A. Stirling, *Isabelle M. Thompson, T. R. Thompson, R. W. Thomson, Marian S. J. Tuszewski, F. A. Tyce, Raymond Veeder, M. O. Waddell, Desmond Walker, Elizabeth A. Waterhouse, Ann C. Wilby, N. V. Wilkinson, C. F. G. Woodman, Joan Yell, Enid M. Young.

*In absentia.

University of Sheffield

At a degree congregation on June 28, the degrees of M.B., CH.B. were conferred on the following:

R. M. Atkinson, K. C. A. Y. Baldwin, James Banner, A. L. Bloom, R. L. Bojankiewicz, H. W. Chambers, Kathleen H. Chrispin, Marjorie Clifton, J. B. Cole M. B. Collins, G. A. Fieldsend, K. B. Holloway, G. G. Imrie, R. S. Johnstone, H. M. Kidd, P. B. Lambert, Fred Lees, F. W. Leigh, Francis Lothe, Marcel Malden, J. D. Parry, Frances B. Penny, N. E. Pitts, Shelagh M. Richards, D. W. M. Rolfe, N. E. Shaw, Mary L. Stewart, Sylvia H. Swift, F. G. Thorpe, David Tingle, I. J. Waite, I. A. Wood, J. K. Young, S. S. Young.

Royal College of Physicians of Ireland

On June 26 Sir Russell Brain, F.R.C.P. Lond., was admitted to honorary fellowship of the college.

On June 27 the following, having passed the final examination of the Conjoint Board of Ireland, were admitted licentiates in medicine and midwifery:

E. St.G. Anderson, K. A. Barrett, John Biggins, M. C. Botha N. R. O'C. Brennan, Nora E. Casey, L. J. Conway, D. J. Daly, K. E. Dewhurst, R. G. Fricker, Ellen C. Geraghty, J. H. Gower, Aileen G. Grant, Stuart Gray, H. C. Henry, J. G. N. Lagan, Leonard Levy, Joan E. Mackey, Joyce W. Malcolm, A. A. Marinho, J. G. Muldoon, Kathleen M. McManus, Kathleen M. McNamara, J. O. P. Noonan, M. A. Okupe, F. W. Quilty, R. J. Regan, J. M. Rennie, Edward Rogan, Celia D. Thomas, J. N. Udom, Veronica Whitty, J. J. Wilson.

Royal College of Surgeons in Ireland

At a meeting of the college on June 3 Mr. M. P. Burke was elected president, and Mr. Ian Fraser vice-president.

Faculty of Radiologists

The following have passed the examination for fellowship of the faculty:

S. Kramer (radiotherapy), F. G. M. Ross (radiodiagnosis), Paul Strickland (radiotherapy), W. N. Thomson (radiodiagnosis), and H. C. Warrington (radiotherapy).

Royal Society of Tropical Medicine and Hygiene

The society will meet at 7.30 P.M. on July 17 at 26, Portland Place, London, W.1, when Brigadier J. S. K. Boyd, F.R.S., will present a symposium on the new antimalarial drug, 'Daraprim.'

Bovine Tuberculosis in Denmark

According to a statement in the *Manchester Guardian* of June 30, the Danish ministry of agriculture has recently announced that eradication of bovine tuberculosis from Danish herds of cattle is now complete. The campaign against the disease began in 1893 with a State subsidy to provide free tuberculin-testing, but thirty years ago 80% of the herds were still regarded as tuberculous.

Lister Institute of Preventive Medicine

Dr. A. A. Miles has been appointed to succeed Sir Alan Drury, F.R.S., as director of the Lister Institute of Preventive Medicine, London.

Dr. Miles, who is 48 years of age, was elected to an exhibition in natural sciences at King's College, Cambridge, in 1921, and completed his medical education at St. Bartholomew's Hospital. He graduated M.B. in 1928 and became M.R.C.P. in 1929. In 1934 he was appointed to the university readership in bacteriology at the British Postgraduate Medical School. Three years later, in 1937 he was elected F.R.C.P. In the same year he was appointed to the university chair of bacteriology tenable at University College Hospital Medical School. This he retained until 1946 when he went to the National Institute for Medical Research. He is at present deputy director of the institute and director of its department of biological standards. Dr. Miles is also a member of the British Pharmacopœia Commission and chairman of the W.H.O. Expert Committee on [illegible] Together with Prof. G. S. Wilson he r[illegible] *Principles of Bacteriology and Immunity.* [illegible] arlier this year.

War Pensions and the Brussels Treaty

By the Brussels Treaty the signatory countries (Belgium, France, Luxembourg, the Netherlands, and the United Kingdom) agreed to develop their social services along corresponding lines. A statement issued after a conference of senior officials from the pensions ministries of the five Powers, held in Paris from June 23 to 26, says that the initial attempt at international negotiation in the field of war pensions has produced some interesting and, in certain cases, notable results. Recommendations submitted to governments by the committee cover the granting, to nationals of the five countries, of medical treatment in respect of accepted war disablement free of charge on the same basis as to nationals of the country of residence. The causal relations of certain diseases with war service have been explored in detail and a guide to the medical bases of assessment of disablement for war victims has been produced.

Scottish South Eastern Regional Hospital Board

The remaining vacancy on this board (see *Lancet*, 1951, i, 813) has been filled by the appointment of Mr. George I. Scott, F.R.C.S.E., who will remain in office until March 31, 1955.

Third Commonwealth Health and Tuberculosis Conference

This conference, organised by the National Association for the Prevention of Tuberculosis, will be held at the Central Hall, Westminster, between July 8 and 11.

World Federation for Mental Health

The federation's fifth annual meeting is to be held at the Université Libre, Brussels, between Aug. 24 and 30. Further information may be had from the General Secretary, National Association for Mental Health, 39, Queen Anne Street, London, W.1.

Pure-tone Audiometry

A memorandum on this subject has been prepared jointly by the Medical Research Council Committees on Medical and Surgical Problems of Diseases of the Ear and on Electro-Acoustics. This memorandum (M.R.C. 52/478) is intended for the guidance both of designers and users.

Institute of Child Health

This institute, in conjunction with the Institute of Education, is arranging a short course on Child Development. The course, which will be held at the Institute of Education, Malet Street, London, W.C.1, from Sept. 29 to Oct. 3, is open to a limited number of consultant pædiatricians and senior pædiatric registrars. Further details may be obtained from the director of the department of child development at the above address.

Views on Nurses

Addressing the Association of Hospital Matrons in London on June 28, Miss Pat Hornsby-Smith, Parliamentary Secretary to the Ministry of Health, observed that since the start of the National Health Service there had been a steady increase in the number of staffed hospital beds and in the total nursing staff. By the end of last March there had been an increase of over 22,000 full-time and 9000 part-time nurses; and the number of staffed beds had increased by over 30,000. However, we still needed many more nurses and a very great number of mental nurses to bring even existing hospitals up to strength and to open all the non-staffed beds that could be used.

Miss Hornsby-Smith continued: "There is some controversy over the age of entry into nursing. It is claimed, and I think rightly, that no young girl should take up training before the age of 18, and that no-one younger should be introduced to scenes of sickness and hospital life. Some even go further and think the right age to be even later. On the other hand, every year sees more and varied forms of employment opened up to young women. If they are keen on nursing at school and possibly have to leave at 16, they may well take up a worth-while job for the intervening two or three years and then not want to leave it. Competition for the educated, able type of young women needed in nursing is keener than ever today. We must be careful to maintain a balance in our decisions so that we overcome these difficulties." At present wastage was at least 40%; and it seemed that this figure was, if anything, on the increase.

"This is a problem calling for very serious investigation—particularly when one considers how large a proportion of those who enter training are from the 18–19 age-group. The number of girls reaching the age of 18 each year at present is about 25% less than immediately before the war, and because of the low birth-rate during the 1930s this number will not increase substantially until 1960. In consequence, the number of entrants has fallen in the last year or so and may well continue to fall. So it is all the more important that a large proportion of those who do take up training should complete it."

Miss Hornsby-Smith reasoned that there was a good deal to be said for nurses living out; this promoted a greater sense of independence and it brought a nurse into closer daily contact with the world outside the hospital. With regard to the National Hospital Service Reserve, the campaign to obtain recruits had so far been disappointing, only some 24,000 having enrolled. It had been estimated that the plans for the operation of the hospital and first-aid services in war-time would entail at least 100,000 extra nursing staff.

Royal Medical Foundation of Epsom College

The annual meeting of governors is to be held at the offices of the Medical Defence Union, Tavistock House South, Tavistock Square, London, W.C.1, on Wednesday, July 16, at 3.30 P.M.

Ministry's Monthly Bulletin

Dr. J. Balfour Kirk, C.M.G., F.R.C.P., has succeeded Dr. J. Alison Glover as editor of section 1 of the *Monthly Bulletin of the Ministry of Health and the Public Health Laboratory Service.*

At the Medical Golfing Society's summer meeting held at the Berkshire Club on June 26, THE LANCET Cup (Scratch) was won by Dr. J. Park, the Henry Morris Cup (Bogey) by Dr. J. Park, and Foursomes by Dr. H. L. Rayner and Dr. Ivor Evans.

Diary of the Week

JULY 6 TO 12

Tuesday, 8th

ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. David Slome: Surgical Research at Downe. (Buckston Browne lecture.)

Wednesday, 9th

IMPERIAL CANCER RESEARCH FUND
5 P.M. (Royal College of Surgeons.) Dr. Peyton Rous, F.R.S.: Carcinogenesis.

BRITISH MEDICAL ASSOCIATION
2.30 P.M. (Royal Institution, Colquitt Street, Liverpool.) Dr. Donald Stewart: Medicine and Employment. (Mackenzie industrial health lecture.)

Thursday, 10th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. Ralph Phillips: Neuroblastoma. (Hunterian lecture.)

INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, W.C.1
5 P.M. Prof. Norman Dott: Subarachnoid Pouch Formations and Allied Conditions of the Cerebrospinal Fluid Circulation.

Friday, 11th

IMPERIAL CANCE[illegible]
5 P.M. (Royal [illegible] Dr. Peyton Rous: Cancer Causes,

Births, Marriages, and Deaths

BIRTHS

[illegible]—On June 24, at Foresterhill, Aberdeen, to Margaret [illegible] of Dr. John S. Caldwell—a daughter.

[illegible] t St. Brenda's Nursing Home, Clifton, [illegible] wife of Dr. A. M. G. Campbell—a daughter.

CLIFT.—On June 21, at Mayday Hospital, Croydon, to Dr. Dorothy Clift (née Newell), wife of Mr. Arthur Clift, F.R.C.S.—a son.

COOKE.—On June 22, at Wokin [illegible] to Mary (née Barney), wife of Dr. G. N. [illegible]

McQUADE.—On June 23, at W [illegible] o Joy (née Manning), wife of Dr. Brian McQuade—a son.

PEARSE.—On June 26, at Hammersmith Hospital, to Elizabeth, wife of Dr. A. G. Everson Pearse—a daughter.

TRIGER.—On June 23, at Goshen, Six Bells, Abertillery, to Olga, wife of Dr. K. Triger—a son.

YORK-MOORE.—On June 25, at the Norfolk and Norwich Hospital, Norwich, to Rosemary (née Williams), wife of Dr. Michael York-Moore—a daughter.

MARRIAGES

MIDDLETON—YUTENKAS.—On June 21, in New York, Peter McKechney Middleton, M.B., to Adele Barbara Yutenkas.

POWELL—WALLS.—On June 21, Peter D. Powell, M.B., of Glasbury-on-Wye, to Jean Mary Walls, of Carston, Ayr.

RUSHTON—FINDLAY.—On June 21, at Chigwell, David H. Rushton, M.B., to Fiona Findlay.

DEATHS

DALGLIESH.—On June 20, at Ipswich Hospital, Frank Bell Dalgliesh, M.R.C.S., lieut.-colonel, R.A.M.C. retd.

LEWIS.—On June 21, in Melbourne, Australia, Ernest Winbolt Lewis, M.B. Edin., late of Codford St. Mary, Wiltshire.

MACLEOD.—On June 22, Neil Ferguson MacLeod, M.B. Glasg., of 61, Uxbridge Road, Hanwell, W.7, aged 34.

SCHAFFTER.—On June 27, Charles Merill Schaffter, O.B.E., M.B. Edin., F.R.C.S.E., of St. Andrews House, Matlock, and late of C.M.S., Isfahan.

STALLARD.—On June 27, Hamilton George Frampton Stallard, L.R.C.P.E., lieut.-colonel, late Egyptian Army and R.A.M.C. retd, [illegible] urt, aged 80.

[illegible] 22, Brigid Stanford (née O'Beirn), M.B. N.U.I., [illegible] d, Scunthorpe, Lincs.

REASON AND UNREASON IN PSYCHOLOGICAL MEDICINE *

E. B. STRAUSS
M.A., D.M. Oxfd, F.R.C.P.
SICIAN FOR PSYCHOLOGICAL MEDICINE, ST. BARTHOLOMEW'S HOSPITAL, LONDON

N my first lecture my purpose was to examine the nciple of causality with a view to ascertaining to what ent it could be made to apply in the field of medicine general and in that of psychological medicine in ticular.

learly, the law of causality requires to possess some vancy and validity if medicine is to maintain any tus in the hierarchy of the natural sciences. It was gested, however, that, if the 19th-century convention almost compulsively searching for efficient causes *usae agentes*), with disregard for the other equally nificant factors in the causal pattern, were persisted in, element of unreason would disorganise the scientific ality, without necessarily violating the laws of formal ic. It was further maintained that this had taken place the case of psychological medicine to a dangerous extent.

Even primitive magic relies on the necessity of ablishing a causal sequence, especially if anything has be *done*, seeing that man is a rational animal. For ample, a tribal rain-maker must have the inner con- tion that, when he pours a bowl of water on the und with the appropriate incantation, the next rainfall s a direct causal relationship with his magical cere- ny. A rain-maker who is not so convinced is a bad n-maker. We shall see later that a psychotherapist— any complexion—who doubts the validity of his own rticular system is a bad psychotherapist. Magic velops into science when it can be shown that the ain of cause and effect is false; and this occurs more ten as the result of trial and error (the experimental ethod) than through pure ratiocination. Inevitably, hemy, which, according to Jung, started as a symbolic, bstitute-religious discipline, developed in this way into emistry.

Let us very briefly review some of the assumed chains cause and effect which have at one time or another termined the theoretical and therapeutic aspects of ychological medicine.

Causal Formulæ in Psychological Medicine

For untold centuries any behaviour-patterns which ave gross offence to the dominant culture-pattern and hich appeared to be unrelated to moral responsibility, understood at the time, were accounted for in terms demoniacal possession. A person barked like a dog, ad fits, talked with unseen persons (or what you will) *cause* he was possessed. Therapeutic procedures, all ependent upon the assumption of this falsely appre- ended causal sequence were various, but all were logical: hole might be bored in the skull to provide a mode of xit for the evil spirit. Ritual exorcism by a qualified ractitioner (priest or shaman) might be regarded as the referred method of treatment. The possessed person ight be required to submit to ill-treatment of various inds—beatings, chainings, brandings, mocking and the ke—so that the body which had been acting as the ost of the possessing demon should be rendered so ncomfortable as to persuade the unwelcome intruder to ake his departure. Treatment of this kind existed in ivilised countries in one form or another until a hundred ears ago. Even in the 18th century in this country a isit to Bethlem to watch the lunatics being ill-treated or to pelt them with filth of all kinds was as popular a Sunday-afternoon expedition as is today a visit to the Zoo to see the sea-lions fed.

The first important departure from this type of magical thinking came with Mesmer's work. This strange 18th-century figure took his medical doctorate in Vienna with a purely astrological thesis, the Effect of the Planets on the Human Body. Mesmer, as you will all know, believed that there was a mysterious vital force, which he called animal magnetism, that could be used to benefit patients suffering from all kinds of mental and bodily disorders. In fact, the term mesmerism has again featured prominently in the general press of this country. A curious, although inverted development of this doctrine is to be found in Christian Science (so called) which still claims many loyal adherents, especially in the United States.

The first serious attempt to formulate some kind of medical-psychological principles and to make use of them to propound a new, relevant causal formula was that of the early hypnotists, especially the members of the so-called Nancy school. They rejected Mesmer's conception of animal magnetism in favour of that of suggestion. They believed that the therapeutic successes of Mesmer and his followers could be accounted for in terms of human suggestibility and that this could be exploited to the best advantage in that altered state of consciousness which they called hypnosis—in preference to the mesmeric trance. It is noteworthy, however, that no satisfactory definition of "suggestion" in scientific psychological terms was forthcoming. It remained almost as mysterious a phenomenon as Mesmer's animal magnetism or Mrs. Eddy's "malicious animal magnetism."

The causal formula was a simple one: mental well-being and acceptable social conduct are the result of "good" suggestions; mental disorder and many forms of delinquency spring from the unwitting acceptance of "bad" suggestions. The logical form of treatment then is, by appropriate counter-suggestions—at first with the use of, at a later date without, hypnosis—to convert "bad" suggestions into "good" ones. In this country, until the beginning of World War I, treatment by suggestion in one of the many forms which it came to assume—hypnotic suggestion, suggestion in the waking state, persuasion (Dubois), re-education (Déjérine and T. A. Ross)—was the main therapeutic standby of the specialists who bothered about treatment at all; and they were few and far between.

During the last quarter of the 19th century great strides were being made in neuro-anatomy and to a lesser extent in neurophysiology. In fact, so much was being found out about the structure of the nervous system and the way it worked that, encouraged by the philosophical climate (materialistic monism and positivism), it was confidently felt in the higher reaches of orthodox medicine that the time was fast approaching when explanations in terms of cause and effect, but of a purely mechanistic nature, covering the whole field of human thought, feeling, and behaviour, would be forthcoming. At one time Oskar and Cecilie Vogt at the old Kaiser Wilhelm Institut, where I visited them once, were engaged in cutting literally millions of sections of the human brain in such a search. I could only admire their ant-like industry, even if I were sceptical as to where it would lead them. (Incidentally, these grand old single-minded research-workers are still alive.)

At the same time, the brilliant researches of Pavlov and his co-workers into the physiology of the conditioned reflex made it appear even more likely to my generation that the naïve approach of Watson in America and his fellow behaviourists would be confirmed by careful physiological observation and experiment. The idea that one can have a psychology without a psyche is anot example, of course, of a failure to apprehend in

---

The second Croonian lecture for 1952, delivered before the Royal College of Physicians of London on May 8. (Abridged.) Lecture I appeared last week.

entirety the principles of causality about which I spoke in my first lecture.

Modern variants of this type of thinking are to be found in Wiener's "cybernetics" which likens the mind (strictly speaking, I suppose, I should say the brain; but people who think on these lines equate the brain and the mind) to an immensely complicated electronic computer. The work of McCulloch is comparable, but endocrinology and biochemistry in general figure more largely in the total schema. Academically less important and well-grounded, but coming out of the same stable, we have Salter's work on "conditioned reflex therapy," and the curious claims of L. R. Hubbard, the transatlantic inventor of "dianetics."

Let me say from the start—i.e., before I embark upon a more detailed and more critical exposé of psycho-analysis—that all these formulations are valuable in so far as they establish partial causal relationships, if only by analogy; and, as we have seen, the causal principles which I have outlined have an important place in their system for *analogical* thinking. It is, I think, unfortunate that most of these original workers and thinkers are or were still thinking in terms of simple paired efficient cause and effect.

In the first of my yearly routine lectures to the students at Barts I warn them that everything that I shall tell them in the first half-dozen lectures is little better, or even nothing more, than an analogy, a parable, a simile, a metaphor, or a mythological construct. This is important, for the kind of psychopathology that I find it justifiable and convenient to teach is a sort of "Freud-without-tears." And I repeat the warning from time to time.

Before Freud

Let me again indulge in a short, somewhat amorphous digression: in my student days we were fully aware of one kind of psychiatrist, the asylum medical officer who had reached medical superintendent status, and more vaguely conscious of another type of mental specialist, the psychotherapist. Those were the early days of the Tavistock Clinic, whose founder and first medical director, Dr. Hugh Crichton-Miller, was even then beginning to put eclectic analytical psychotherapy on the map. There were also at that time a few courageous pioneer workers in Freudian psycho-analysis. The majority of us students regarded this second category as "mystery men" whom we treated with a certain amount of amused respect, but failed to take quite seriously. The first category were acceptable in view of the fact that all that they had to teach us was descriptive psychiatry, which did not compel us to indulge in any strenuous thinking for ourselves. Even then it must be admitted that we regarded our few compulsory attendances at a mental hospital for lecture-demonstrations more as a diverting tea-fight than as a serious part of our studies. I think that it would be fair to say that in those days, at least, the most successful mental specialists were those who could demonstrate psychotic "case-material" most effectively, or, to put it less gently, were the best showmen.

Even today the climate surrounding the practising psychiatrist is somewhat anomalous. Nowadays even those who have never heard of Freud are thinking altogether differently from those who lived in pre-Freudian times. Every now and then geniuses appear who reshape our pattern of thinking in this way. Such names as Newton, Karl Marx, Sherrington, Einstein, Planck, occur to us in this connection. The result is that, whereas in the times that I have just described Freud and his courageous followers, if they were heard of at all, were looked upon as prurient-minded cranks, today Freud's basic teaching is not only regarded as being respectable but is taken for granted—i.e., uncritically accepted. In those days it would have been ungallant and "reactionary" to have attacked psycho-analysis—many did so, however; but now that psycho-analytical theory and practice have become modern orthodoxy, it is perhaps a duty on the part of those who feel that their long experience has given them grounds for relevant criticism to speak without fear or favour.

It must not be forgotten that Freud's basic training was neurological and that he was at one time a pupil of Charcot in Paris. It is therefore not surprising that, when he came to think independently, he should have done so in the terms of simple cause and effect derived from the physical sciences. This reliance on formal logic, however falsely based, proved very attractive to the scientific mind and finally succeeded in overcoming the violent opposition—largely based on prejudice and prudishness, as it was at the time—to which it had given rise.

It must not be supposed that the concept of unconscious mental processes originated with Freud. The notion is to be found in the writings of St. Augustine and St. Thomas Aquinas; and, in Freud's own time, von Hartmann had attempted to base a philosophical system upon it. However, Freud was undoubtedly the first to conceive of the immense possibilities of applying this notion to the problem of human motivations in health and disease and thereby revolutionising for all time the whole of normal and abnormal psychology.

This is obviously neither the time nor the place to attempt to summarise the whole corpus of Freudian doctrine and practice. It should, however, be emphasised from the start that Freud's ingrained habit of searching for a simple efficient cause to account for a sequence of effects, however complicated, led to a doctrine of psychological and philosophical determinism of a more far-reaching kind than had ever been previously known, and to the triumph of the principle of unreason in psychological medicine.

The Triumph of Unreason

It never seems to have occurred to Freud or to his disciples, orthodox and dissident, that science and philosophy can accept and make use of the factor of random chance, and that a system of psychology that excludes the fact of human volition from serious consideration is bound to come to grief sooner or later, if only for the reason that it fails to conform to human experience.

The extent to which Freud's teaching on this point is most clearly shown is perhaps best exemplified in his little book, *The Psychopathology of Everyday Life*, a work which became so popular that it was even issued as a "Penguin." If I leave my umbrella in a friend's house, it must be (not it may be, mark you) because I harbour an unconscious desire to have a respectable excuse to revisit the house. If the maid (when Freud was writing, there were such things as maids) breaks the best china teapot, it must be because she is giving expression to her unconscious resentment at being in service at all. All forgetting is purposeful even if the purpose remains unconscious.

We are thus presented with a psychological schema which is more teleological than anything that the most rigid moral theologian could devise, and a doctrine of causality borrowed from physics (without there being any obvious recognition of its analogical nature) which baulks at the First Cause. (It will be remembered that the First Cause is taken out of its causal framework and nonchalantly presented to us on a Freudian plate as a mere skyward projection of the "father-image.")

The life of man, like that of any other animal, is governed by the pleasure-pain principle, and in the last analysis by nothing more. This means that our sole motivations can be reduced to the desire to experience pleasure and to dodge pain; or, expressed in more "neurophysiological" terms, to avoid unbearable tensions. It is interesting that the prophet of the primacy of ex (for all pleasure, according to Freud, is ultimately sex-derived) should have lost sight of the fact that man alone of all the animals can artificially create almost unbearable tensions just in order to relieve them, and that the tension is just as essential a factor in the total pleasure-complex as its relief. An explanation of this apparent paradox by making use of such terms as sado-masochism is, in the opinion of many, a semantic trick and not a true explanation.

"TREATMENT OF CAUSES"

As indicated earlier, the great advantage of the Freudian system was that, in its therapeutic application, it claimed to treat the causes of symptoms rather than symptoms merely. The great disadvantage of the suggestive methods was that, although they were often successful in abolishing the troublesome symptoms of the moment, they were apt to return after a while either in their previous or in some other form—but not always, be it remembered.

Every patient who starts an analysis is told, explicitly or implicitly, that his symptoms have a meaning (i.e., a cause), that this causal relationship exists at that level of the mind which we call the Unconscious (with a capital U), and that he will be relieved of his symptoms once and for all as soon as this relationship is brought into consciousness with emotional conviction, even if the search takes many years, as it may well do.

The analyst, on the other hand, goes to work with a somewhat different formula: the cure of any neurosis, psychosis, or psychosomatic illness depends on the conversion of the *actual* neurosis into a *transference* neurosis and the subsequent resolution of the latter. According to the psycho-analysts, a special kind of dynamic relationship is set up between the analyst and the analysand (patient, or sometimes trainee-analyst). Almost from the start, the analyst becomes identified with one or other of the important figures in the primal childhood drama—usually the mother or the father or a parent-substitute, or each in turn. In the course of analysis the primitive emotions with their polar opposites are *transferred* (hence the term "transference") to the person of the analyst, who is in turn extravagantly loved and equally extravagantly hated. Since these early ambivalent attachments contain a strong (repressed) incestuous element, the attitude of the analysand to the analyst comes to be sexually over-determined. This constitutes the transference neurosis, whose final resolution (largely by active interpretation), if it ever takes place, terminates the analysis. The "actual neurosis," which in the course of successful analysis is replaced by the transference neurosis, is represented by the intolerable symptom-complex for which the analysand is seeking permanent relief.

In view of the incestuous element invariably present in the child-parent or inter-sibling relationship already mentioned, the well-known Œdipus complex (and/or its inversion) is ineluctably disclosed in the course of analysis. In fact, no analysis can be said to be complete until this happens, since failure to resolve the Œdipus complex is said to be the final cause of most mental disorders.

The readiness with which the transference neurosis can replace the actual neurosis depends on the principle of repetition-compulsion, which states that, once a subjectively uncomfortable or socially unacceptable form of canalisation of these infantile, sex-derived emotional dispositions has established itself, it will continue to repeat itself in an increasingly adult setting until the actual neurosis crystallises out as a stable construct. There is no way of meeting this impasse other than through the analytical procedure just described.

I know that this account of the Freudian attitude to the therapeutic aspects of their discipline is a gross over-simplification; but it is not inaccurate. Further, my future critics will complain that I am giving a wrong definition of or a wrong twist to such terms as transference-neurosis or repetition-compulsion. However, this is inevitable, for Freud himself over the length of the years and in his rich output gives different connotations to the terminology of his own coinage; and no two psycho-analytical writers seem to agree exactly on correct usage. The way in which convinced analysts meet scientific and philosophical criticism will call for some comment later.

Many of the assumptions of psycho-analysis which contribute to the element of "unreason" in psychological medicine will already be apparent; others will require further exposition.

It may be said, however, that this remarkable and admirably worked-out *closed* system provides a ready-made (or a potentially prefabricated) answer to all the problems of man's action, feeling, and thinking patterns both in health and disease. Anxiety (whatever the actual situation might be which makes anxiety inevitable) is due to guilt arising out of the unconscious residua of out-of-date psychosexual dispositions. Depression is caused by repressed aggression (itself a by-product of sexuality) directed against the ego. Hysteria depends on a "fixation of the libido" at a pregenital level, obsessive-compulsive neurosis on anal-erotic dispositions (likewise depression, incidentally). Schizophrenia is rooted in primary narcissism and is hence psychogenic. Homosexuality (like almost everything else, in the last analysis) depends on a failure to resolve the Œdipus complex. And so on, and so on.

All these answers depend on the assumption that the questions themselves can be put in the form: "what is the efficient cause of this or that effect?" There is of course the further assumption that the efficient cause is invariably psychic.

As my main thesis is that specifically human situations cannot be stated in terms of simple cause and effect, and, as I regard the principle of multiple ætiology as valid throughout the field of medicine, I am bound to reject much of psycho-analytical doctrine as an irrational system and to regret its *unselective* application as a therapeutic instrument.

THE PRAGMATIC TEST

In the long run, the only sound test for the therapeutic aspects of any branch of medicine is the pragmatic one. If orthodox psycho-analysis could pass this test, it could afford to snap its fingers at its armchair critics. What are the facts? Significant statistical data are lacking, but it would seem that, even in the best hands and with the treatment unhampered by lack of time, psycho-analysis can claim only 22–25% of satisfactory cures. This is disappointing, to say the least, in the case of a system which states that, once the simple chain of cause and effect has been established in the depths of the psychic structure, cure is automatic and inevitable. If this belief is shared by analyst and analysand alike, treatment may well continue indefinitely or until the patient's financial resources are exhausted. That must be so if cure is always thought to be just round the corner. In 1934, for example, I knew of an obsessive-compulsive neurotic patient who had been attending a reputable psycho-analyst for five one-hour sessions a week for the past eleven years. For all I know, he is still undergoing psycho-analysis.

How then are we to account for the 25% of successes (taking the higher figure)? So far as the less well-established *psychoneurotic* formations are concerned, it may be said that some 25% of patients appear to benefit considerably from psychotherapeutic procedures which are unrelated to depth-psychology in the Freudian sense, and that it seems likely that analytical psychotherapy which regards itself as free to depart widely from the orthodox psycho-analytical technique and is sceptical about large parts of Freudian theory can claim a considerably larger number of satisfactory successes than those obtained by rigid orthodox analysts.

CAUSE OR PHASE ?

I am one of those who maintain on the grounds of experience that concepts such as the Œdipus complex, infantile sexuality, and the like mean something and are valuable. However, the use to which they are put by practising analysts is often unfortunate. Freud himself in parts of his writings describes these potential patterns of conduct and feeling as belonging to the natural history of development. In other places, the inference is that these repressed elements are inevitably pathogenic; and the average orthodox analyst pounces on indications of these ontogenetic psychic residua with glee, as they crop up in dreams and free association, as ineluctably providing important clues to the *causation* of the actual neurosis. In my opinion, psychic elements of this kind, as in the case of all kinds of human experience (actual or potential), *may* figure in the pattern of faulty adaptation which we call a psychoneurosis, but analysis may equally well be uncovering traces of natural history possessing no kind of pathogenic significance. To be a little more specific: an analyst over a few years, let us say, analyses half a dozen obsessive-compulsive neurotics and (with or without a certain amount of tendentious suggestions) discovers evidence of buried anal-erotic dispositions in all of them. The immediate inference for this analyst, who is steeped, let us suppose, in Freudian doctrine, is that anal erotism (so called) is the efficient cause or one of the *causae agentes* of obsessive-compulsive neurosis. If, however, "we turn to another page of the book," we find that anal erotism is one of the stages of libidinal development through which we all pass; and it is a logical inference that a control group of normal analysands would also provide evidence of their anal-erotic components. This is only a polite way of expressing the homely truth that one cannot always have it both ways.

In the same sort of context, let us examine the generally accepted psycho-analytical theory of the genesis of homosexuality (in the male, let us say, to keep things as simple as possible). Psycho-analysts maintain that the efficient cause of homosexuality is failure to resolve the Œdipus complex, with the result that after puberty all women become unconsciously tarred with the incestuous brush, causing the adolescent male to regress to the homosexual phase of libidinal development—which, incidentally, and I think with a certain amount of correctness, is postulated as a bit of natural history—and remains stuck, or "fixated," to use Freudian terminology. That formulation, nevertheless, leaves several very important questions unanswered, especially if one is thinking in strictly causal terms. For example, why is this particular boy "mother fixated"? Is it not equally likely that this boy, in view of his asthenic temperamental endowment, established an over-strong emotional dependence on his mother, needing from the start a greater measure of protection from "the slings and arrows of outrageous fortune" than his more robust brother? This would provide an equally valid part-interpretation of homosexuality in terms of constitutional temperament and genetic equipment; and it could not be maintained, I think, that it would be possible to reduce a gene or a constellation of genes to their psycho-analytical terms.

MULTIPLE ÆTIOLOGY

These considerations justify my pointing out in slightly greater detail to what an extent rigid psycho-analytical theory violates the principle of multiple ætiology that I mentioned in my first lecture: for example, Freud himself was by no means blind to the genetic factor. For instance, realising, as he did, that elements of this kind could prove resistant to his technique, he warned his followers against employing it in the case of the psychoses. Many psycho-analysts since then have been less cautious. It could not be denied, I think, that schizophrenia would not develop in the absence of a specific major inheritance factor. Whether this gene predisposes to a certain kind of biochemical perversion at the level of the hypothalamus, as seems quite likely in the light of our present knowledge, or whether it brings about a fragmentation of the personality-structure in other ways is hard to determine. Nevertheless, the only factor which lends itself to psychological analysis (and the psycho-analytical method proves itself to be an inefficient and clumsy instrument for such an analysis) is the precipitating factor; and the analysis would show that the component elements were just as much social or environmental as psychological. In spite of Dr. J. R. Rosen's interesting claims, I would take leave to doubt whether the benefit that his schizophrenic patients derived from his technique could be explained in the strictly causal terms demanded by Freudian theory.

Again, the genetic element in cyclophrenia (as I prefer to call manic-depressive psychosis) is equally definite; and the biochemical determinants of involutional depression are clearly important. Yet the fanatical psychogeneticists amongst the psycho-analysts are bitterly opposed to electroplexy and all physical methods of treatment in these and in other psychotic disorders. The grounds for their disapproval are interesting: they object to therapeutic measures which are empirical in nature (i.e., do not appear to be expressible in terms of simple causality); and they also resent the fact that, if one cures the depressive or the manic attack of the moment without employing the psycho-analytical method, one gets to learn nothing about the psychopathology of cyclophrenia—and this quite regardless of the fact that psychopathology may well represent a glaring irrelevancy. The statement (already mentioned) that in depressive states aggression is directed against the self instead of being projected on to elements in the outside world is a descriptive account and in no sense an explanation in causal terms, as alleged. Furthermore, this provides an instance of the objectionable facility with which psycho-analysts concretise the abstractions of their own devising, so that they come to think of "aggression" as though it were some kind of corrosive fluid under pressure capable of being conducted into this or that channel. In point of fact, of course, there is no such *thing* as aggression; all that there is is an angry man prepared to launch an attack—in other words, an actual or potential pattern of conduct or feeling.

Other instances of the concretisation of psycho-analytical abstractions which are in the last analysis nothing more than semantic conveniences will occur to all of you readily enough. The various divisions of the psyche in the Freudian schema—ego, super-ego, and id—are apt to be regarded as such concrete realities that their representation in terms of cerebral architectonics is occasionally sought for, at least in fantasy.

Towards the end of this lecture I will give my own views of the road which our vast ignorance of the real determinants of mental and emotional disorders entitles us to follow. But, whilst humbly recognising the great debt which psychiatry owes to Freud, I find it necessary to point out here that the psycho-analytical formulations by no means exhaust even the psychological possibilities.

SHORTCOMINGS OF THE PSYCHO-ANALYSTS

You will remember that, in his approach to "depth-psychology," Jung is less interested in clear-cut, sex-derived dispositions arising out of individual experiences, and pays more attention to the balance or tensions associated with the "faculties." Blake, with the vision of the mystical prophet and inspired poet, approached the endopsychic drama in a strikingly similar way. Let me quote from Professor Blackstone's book, *English Blake*, in illustration of this. He is commenting on Blake's *The Four Zoas*:

> "The Eternal Man who is 'in the beginning' lives ideally in enjoyment of every aspect of his being. Of these aspects four are prominent: the imagination (Los), the reason (Urizen), the passions (Luvah), and the instincts or body (Tharmas). So long as these aspects are held in fluid interplay, all is well. But Man (Albion) is led astray by his passions, and begins to worship them. He permits himself to be dominated by Luvah, and only recovers in time to appeal to Urizen for help. But already the balance of consciousness has been disturbed—the excess in the direction of passion has to be remedied by an excess in the direction of reason. Urizen seizes all power into his hands, banishes Luvah, and initiates the egotistic universe of matter. Tharmas is precipitated in a material form as the ocean, and Los, separating from his emanation Enitharmon (inspiration), is engaged in an eternal struggle from now on to redeem man from the effects of his folly. This involves warfare with Urizen. Man falls into the world of generation, and the phenomenal universe is detached from his body."

The psycho-analysts, over-fascinated as they are by the natural or psychopathological history of the early libidinal drives, remain blind to psychological possibilities of this kind, which seem to me to represent equally important features of the human situation.

Before we turn from this brief, critical survey of the orthodox psycho-analytical position and consider other aspects of psychological medicine from the standpoint of reason or unreason, may I present you with another quotation, this time from my introduction to Roland Dalbiez's *Psychoanalytical Method and the Doctrine of Freud*. I regard my comment as being of some importance, because it perhaps serves to show how it came about that the work of Freud and of his more gifted collaborators which would have benefited so much from honest scientific and philosophical criticism was protected therefrom:

> "The psychoanalytical movement itself, however, has developed on extraordinary lines. It has come to resemble a cult more than a scientific discipline. It has its canonical literature, its apocryphas, its orthodoxies and heterodoxies, its inquisitors and its apostolic succession. Orthodox psychoanalysts are compelled to submit their will and reason to as stern a discipline as any members of a Religious Order. Thus it comes about that many psychoanalysts inhabit a little world of their own that is apt to be quite out of touch with systems of thought which are foreign to them."

Physical Methods in Psychiatry

I will have very little to say about the physical methods of treatment which have found a place in the modern practice of psychological medicine. The way in which they fit into the categories of reason and unreason is clear enough. The more prudent protagonist of any of these methods would not claim that they are rational; they are all empirical, and many of them developed out of observations and hypotheses which subsequently turned out to be irrelevant from the strictly rational point of view. This is nothing new in medicine, of course. We need only remind ourselves of the false premises on which Wassermann erected his test. These physical methods will survive for so long as they pass the pragmatic test, until they are superseded by other methods which give better therapeutic results; or, to use an Americanism, they will be used so long as they continue to "deliver the goods."

I, for example, am satisfied that the best method we have today of treating the depressive syndrome in carefully selected cases is by electrically induced convulsions, provided that the technique is sound and that apparatus is used which reduces the risk of damage to neurones to an absolute minimum. However, I recognise the fact that the introduction of a more satisfactory procedure might cause me to reverse this opinion at any moment. As other examples: the popularity of hypoglycæmic coma in the treatment of schizophrenia is on the wane, especially in the United States, where it enjoyed its peak-boom; and I would venture to prophesy, perhaps rashly, that the time is not far distant when prefrontal leucotomy will have been relegated to the museum of grim, outmoded neurosurgical curiosities, even though the procedure is justifiable today, in certain cases.

The Rational Basis

To revert once more to orthodox psycho-analysis in relation to the pragmatic test: it is a curious, but undoubted, fact that the psycho-analytical method can claim the least number of successes in the very field in which its theory is rooted. The number of "cures" of patients exhibiting clear-cut psychosexual anomalies is disappointingly small. I have, for example, yet to come across a case of well-established sexual fetishism which responded satisfactorily to psycho-analysis. The late Dr. Stekel, a non-conforming psycho-analyst, in his two-volume study of fetishism, makes no clear claims to therapeutic successes, although he enjoyed great prestige as a successful psychotherapist in other fields.

I do not wish to give the impression that it is impossible to establish a simple cause-and-effect relationship at the psychological level, but it is likely that this occurs about as rarely in this field as in that of general medicine. As an example, I might quote the following case:

> A young man complained of nausea and vomiting in taxis. It was not a case of ordinary car-sickness, since he was affected only in cabs in this way. The following history was elicited under hypnosis: at the age of 12 on the way home from school he had smoked a cigarette in the taxi and had promptly vomited. At the time smoking by preparatory schoolboys was regarded as a considerable crime; his guilt-sense (presumably) caused him to repress the memory of the incident together with its emotional investment. The knowledge of the "meaning" of his monosymptomatic neurosis led to its abolition.

It is just as legitimate to think of a neurotic symptom of this kind in terms of conditioned reflexes and its cure as the extinction of a conditioned reflex, as to rely on an interpretation based on the Freudian concept of repetition-compulsion.

At the very beginning of his independent work in the field of psychological medicine, Freud employed hypnosis in this way, in the belief that there was always a causal relationship between a repressed traumatic incident and the presenting symptom-complex. That is one of the reasons, perhaps, why, even after he was able to throw light on the immense complexity of the depths of the human psyche, he stuck to his over-simplified notions of causality.

What is to be done to avoid the element of unreason in analytical psychotherapy, and is it really of any practical consequence to do so? To answer the second half of this question first: in the case of psycho-analysis, at any rate, it is important to review its rational basis, for psycho-analysis claims to be more than a corpus of knowledge forming the basis of a therapeutic technique. It claims to act as a guide for the bringing up of children and their subsequent education, to act as a substitute for dogmatic theology, to offer reliable rules for literary and artistic criticism, to reinterpret history, to provide a solution in psychological terms for the problem of war, to reformulate the moral principle of human responsibility, and much else. Quite apart from these general considerations, which are of no immediate interest to the physician, it seems likely that a therapeutic discipline in which the practitioner is unable to differentiate between reason and unreason is bound to give equivocal and incalculable results.

To answer the first half of the question: it seems to me necessary to state the problem itself in simple terms. If one's primary formulation is elaborate, the answers that follow are likely to be so complex that the philosophical framework that should contain them breaks up.

I would be content to say, with Curran and Guttmann, that a mental illness represents a failure to adapt to the situation of the moment, and to commit myself no further so far as definition is concerned. Such a simple formula allows one to employ deduction and induction, and argue *a priori* and *a posteriori* as the occasion demands. It also has the great advantage of conforming to the principle of multiple ætiology. For, clearly, a failure to adapt to a given situation may depend primarily on bodily, psychic, constitutional, genetic, social, or (I would be so bold as to add) spiritual factors.

Furthermore, this formulation makes it essential to take the current conflict into account in arriving at an assessment of the total situation. The psycho-analysts attribute secondary significance only to current difficulties. They regard them merely as representing a trigger or a precipitating factor for starting machinery which is already assembled in the unconscious. The unreason involved in such a notion should, I think, be sufficiently obvious. The problems of infancy, early childhood, pubescence, married life, involution, and senescence, and those associated with approaching bankruptcy, shall we say, or threatened divorce proceedings, imprisonment, or a loss of religious faith, are fundamentally different in kind one from another; it is not just a difference of degree. It seems to me foolish to maintain that early libidinal frustrations are not only the paradigm of more adult discontents but that, in accordance with the psycho-analytical mystique, the pattern is endlessly repeated.

In a sense, the situations to which we are required to adjust are the same throughout our lives, if we reduce the subjective unease involved to its simplest terms: we have to learn by means of foresight to sacrifice the satisfaction of vital (immediacy) values to more realistic needs projected into the future. However, the social setting in which this occurs and the equipment which enables us to try and meet the challenge vary so much from life-phase to life-phase, that it is both irrational and unpractical to insist on the identity. Thus, the failure to adjust to the total situation in the case of a young man who is, say, unconsciously seeking a mother-substitute instead of a mate is in no truly meaningful sense identical with the similar problem which was presented to our hypothetical patient in early childhood. Nor is there any compelling reason to suppose that putting the wheel of time into reverse by taking him for a ride in the psycho-analytical time-machine and forcing him to review his infantile conflict in fantasy is in itself—however skilfully the transference-situation is handled—going to help him to make a satisfactory adjustment to actuality.

Furthermore, it must be remembered that certain acquired psychosomatic patterns have the character of irreversibility; in other words, the psychotherapist is not omnipotent, whatever instrument he may choose to employ. As an example of an irreversible pattern of this kind: an able psycho-analyst has recently shown that the lengthy separation of an infant from his mother or an accepted mother-substitute can so vitiate the emotional organisation of that child that he can never thereafter enjoy proper human relationships.

DIAGNOSIS

As in general medicine, then, so in psychiatry: accurate diagnosis must precede treatment; nor does diagnosis mean merely the neat attachment of a nosological label to a symptom-complex. Such labels are eventually necessary for the compilation of statistical tables, but as a guide to treatment they are even less helpful in psychological medicine than they are in the general field. A patient may be exhibiting anxiety together with its somatic accompaniments as the main presenting syndrome, but it would be unwise in the extreme to make a lightning diagnosis of anxiety neurosis; for a fuller investigation may show that the correct diagnosis may well be early thyrotoxicosis, or incipient schizophrenia, or concealed endogenous depressive psychosis; in fact there are a hundred and one diagnostic possibilities in every case. After he has taken a full history, a psychiatrist should be able to provide answers to all the questions which arise naturally from the principle of multiple ætiology.

TREATMENT

In treatment, then, a psychiatrist must be prepared to try to influence the total situation on several fronts, which include the somatic, the psychic, and the environmental (in its most inclusive sense). Constitutional and genetic factors must be carefully considered in the ætiological assessment, even though they may not be modifiable.

For example, after the initial interview a psychiatrist may decide that all that is required to enable a child who is reacting neurotically to the actual situation is to arrange for a change of school or foster-parents, and that consulting-room methods of treatment, such as interpretative play-therapy, might be positively contra-indicated. Nevertheless, it must, in my opinion, be taken as a general rule that the psychotherapy of adults should always include a careful analysis. This analysis should invariably embrace the total situation of the moment together with all the associated current conflicts. It will in most cases soon become apparent whether the analysis should be extended into the depths of the psyche. It must always be gratefully remembered that even for a proper psychological appreciation of the actual situation we shall always have to rely to a large extent on the pioneer studies in depth-psychology of psychopathologists of genius such as Freud, Jung, and Adler. Nevertheless, it must not be forgotten that in many cases of psychoneurosis all that can be established is the operation of diffuse psychic tension or a non-purposeful psychic content which is reacting on the autonomic nervous centres in such a way as to bring about considerable psychic disequilibrium (Kretschmer).

When we are making use of any of the analytical techniques which have proved of value—and they are many—we should always try to be clear in our own minds whether we are employing *analogical* thinking or dealing with "true" causal sequences.

Further, a psychiatrist should feel free to employ all non-analytical methods as the occasion demands. These will include the physical methods, re-educative methods, direct and indirect suggestive methods, abreactive methods with the use of hypnosis or drugs, conditioned-reflex therapy (Salter), Yoga-like methods such as Schultz's "autogenes training," and Kretschmer's fractional hypnosis, and many others. There is, needless to say, one essential proviso: the practitioner must be a past-master of the technique which he is employing and have a complete belief in its efficacy for the task in hand. Furthermore, every psychiatrist should be a competent general physician with a considerable knowledge of neurology and biochemistry. It will be apparent that I uncompromisingly reject the admission of medically unqualified practitioners into psychological medicine. Certain well-trained and especially gifted lay men and women may, however, render valuable assistance in some highly specialised fields such as play-therapy.

The Psychiatrist

Before I conclude these lectures, even at the risk of appearing to introduce an irrelevancy, I should like to mention one more result of the holding of a *credo* of unreason: both in this country and in the United States there are many posts in mental hygiene which are advertised with a clause limiting applicants to those who have undergone a personal analysis. This implies that we have reached a stage in our social evolution when a new kind of aristocracy, "the fully analysed," has appeared on the horizon, together with a novel sort of proletariat, those who have not done their drill on the psychoanalytical barrack-square and those who have seen fit to dissociate themselves from the Freudian chiaroscuro. Holding the views that I have endeavoured to set out here, I am always embarrassed when other members of a selection committee on which I may happen to be serving ask a candidate for an important psychiatric post whether he has undergone a personal analysis or not. An affirmative answer, as things are at present, is bound to count unduly in his favour with some and to damn him out of hand with others.

The psychiatrist today is in a peculiar position vis-à-vis his professional colleagues in other branches of medicine. As I hinted earlier, thirty or more years ago there was one class of alienist who was called in to certify one's insane patients. Between whiles for the most part such a practitioner did no more damage than prescribe too much bromide, thereby occasioning a few cases of undiagnosed bromide intoxication. Another class of mental specialist exercised custodial functions behind the high walls of mental hospitals and organised cricket matches. The modern psychiatrist presents a challenge; and the attitude to him is curiously ambivalent: at the same time as he is regarded with a considerable measure of suspicion, and accordingly comes in for a fair amount of (sometimes rather ill-natured) banter, he is quite confidently expected to work therapeutic miracles, and in double-quick time; and, strangely enough, he often comes up to expectation.

It must be remembered that from the scientific point of view psychiatry is some fifty years behind general medicine. If psychiatrists will only bear this in mind and not expose themselves to the charge of being "enthusiasts," in the 18th-century sense of the word, they will realise that this double-edged attitude is inevitable for the time being. To console themselves, they can tell themselves that the future of psychological medicine is bright indeed, perhaps brighter than in any other field, and that its rate of progress is such as should satisfy even the most impatient.

DEGENERATION OF THE SPINAL CORD ASSOCIATED WITH CERVICAL SPONDYLOSIS

Stookey in 1928 described degeneration of the spinal cord in association with cartilaginous protrusions into the cervical region of the spinal canal. These he then called chondromas, but later (1940) he accepted the view that they were the disc protrusions originally described by von Luschka (1858). Further studies of the syndrome have been made by Russell Brain et al. (1948), Epstein and Davidoff (1951), Spillane and Lloyd (1951), Allen (1952), and others.

In most instances the syndrome develops not in relation to an isolated disc protrusion but as a part of severe spondylotic changes in the cervical spine, which may or may not show much protrusion of the degenerated intervertebral discs. The mechanisms whereby the cord degenerates in relation to this spinal disease are often quite uncertain. The case reported here illustrates some of the many factors which have to be considered in attempting to unravel the causes of the myelopathy.

CASE-RECORD

Mrs. A, aged 71, during the autumn of 1949 complained of pains which "started from my toes and ran all the way up the front of my legs." Between these paroxysms of pain there was a dull ache in both legs, not confined to the joints. As far back as 1946 she had had acute attacks of pain in the legs, which had subsided spontaneously after a few days.

Towards the middle of 1950 she complained of weakness of the legs as well as of pain, and of numbness of the right hand and forearm. Incontinence of urine developed in December, 1950, and severe constipation led to her admission to the Radcliffe Infirmary with intestinal obstruction. Enemata relieved the bowel difficulty, but by then bed-sores had developed. She was sent home on Jan. 4, 1951, and admitted to Cowley Road Hospital on Jan. 30, 1951.

Neurological examination revealed spastic paresis of both lower limbs, especially the right, which was powerless and had developed a flexion contracture (correctable to 170° with pain). The ankle-jerks were brisk, but the right knee-jerk was absent and the left sluggish. The right plantar reflex was extensor, and the left doubtful. Postural sense was lost over both lower limbs, but pain and temperature sense were lost only on the left, up to about D9, giving a partial Brown-Séquard syndrome. The right upper limb was weak, and there was obvious wasting of all the small muscles of the hand. The right arm reflexes were greatly depressed, while those of the left arm were normal. No sensory loss was detected in the arms, but detailed examination was not possible.

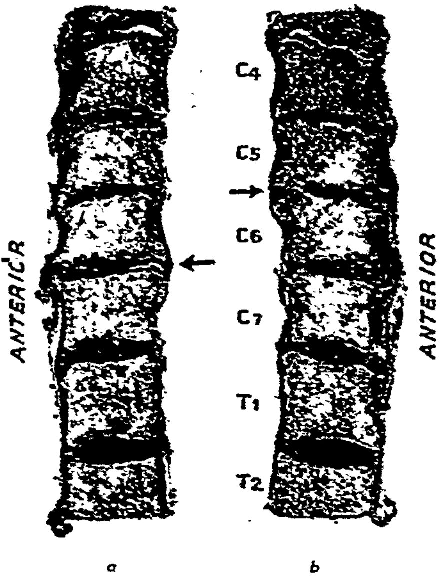

Fig. 1—Parasagittal sections of cervical spine through the two protrusions seen in fig. 4 (marked by arrows): *a*, left; *b*, right, showing degeneration of discs and osteophytic lipping. T1 (left) shows protrusion of degenerated disc material into vertebral bodies (Schmorl's nodes).

Lumbar Puncture.—The lumbar cerebrospinal fluid (C.S.F.) on Jan. 30 was under a pressure of 120 mm. of water. On jugular compression there was a very slow rise of 40 mm., followed by a similar slow fall on release. The C.S.F. contained total protein 90 mg. per 100 ml. and 1 cell per c.mm.; the Lange curve was negative, as also were the Wassermann and Kahn reactions. Re-examined on Feb. 19, the C.S.F. contained 105 mg. of protein per 100 ml. and 2 lymphocytes per c.mm.

Blood Examination.—The serum-protein level was 6·8 g. per 100 ml., and a blood-count showed 10,000 white cells per c.mm. and hæmoglobin 77%. The erythrocyte-sedimentation rate was 116 mm. in 1 hour. The blood Wassermann and Kahn were negative.

Radiography on Feb. 1 showed elevation of the right diaphragm with partial collapse of the right lung; and well-marked degenerative changes in the spine with narrowing of the disc spaces and osteophytic outgrowths at many levels. These were most conspicuous in the lumbar region, but in view of the clinical picture the changes in the cervical vertebræ were thought to be the more significant.

Treatment.—The patient was unfit for laminectomy. An attempt was made to apply neck traction, but death occurred on May 20, 1951.

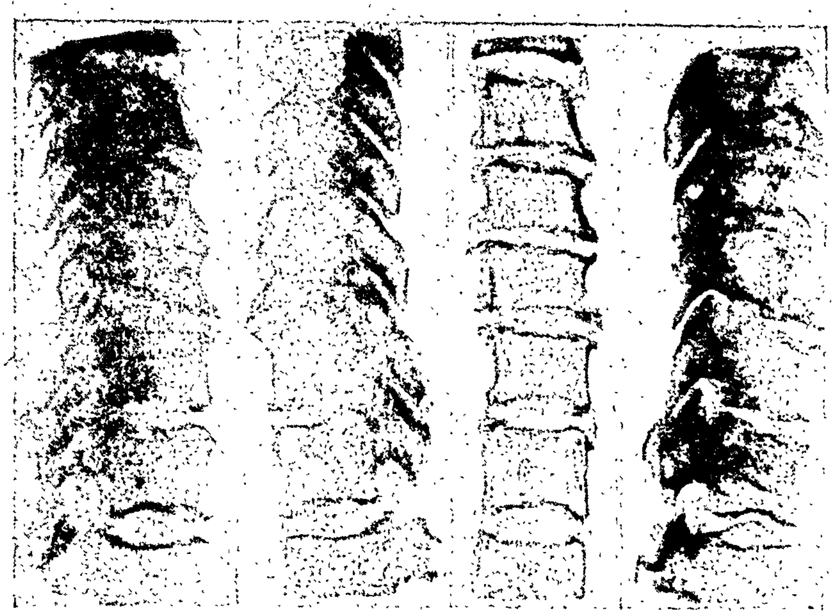

Fig. 2—Lateral radiographs of cervical spine (removed): a, intact specimen; b, left, centre, and right slices obtained by two parasagittal sections.

Necropsy confirmed the severity of the spinal disease in the cervical region. Though nearly all the cervical intervertebral discs were somewhat prominent when viewed through the opened spinal canal, those between c5 and c6 and between c6 and c7 projected most and formed well-marked ridges which expanded laterally into two discrete osteophytic protrusions (fig. 4b), that on the left between c6 and c7 being the larger and projecting about 4 mm. The 7th cervical nerve passing over this spur was stretched and atrophic. Sections through the vertebræ showed that all the cervical discs were degenerated and thinned, and that the prominences were formed by protrusion of the discs covered by bony outgrowths (osteophytic lipping) from the edge of the vertebræ. This change had taken place *not only on the posterior surface* but also round the whole rim of the vertebral bodies, and was in some cases accompanied by severe sclerosis of the bone (figs. 1 and 2). Laterally the process had encroached on the intervertebral foramina, and oblique radiographs of the specimen (after section) showed well the amount of narrowing and distortion (fig. 3). These are the changes of spondylosis *deformans, known in the past as osteo-arthritis of the spine.*

The spinal theca was adherent to the posterior longitudinal ligament at the level of the protrusion at c6–7, and it had been held against the bone firmly enough for the spurs to cause indentation (fig. 4). The spinal cord throughout the whole extent of what should have been the cervical enlargement was much shrunken, as is well seen in fig. 5, and in the 7th and 6th *segments the anteroposterior diameter of the cord was reduced* to 0·4 cm. There was, however, no kinking of the cord, and in spite of the slight protrusions into the spinal canal the theca lay quite loosely over the dorsal surface of the wasted cord.

PATHOLOGY

Microscopy of the cord showed some interesting features. The *chronic degenerative lesion of the cord* was most severe in the 5th and 6th cervical segments, with secondary degeneration ascending and descending from it. In these two segments there was degeneration of both the grey and white matter, with diffuse loss of nerve-cells and severe gliosis (fig. 6). It will be noticed in this figure that the pia mater, especially the denticulate ligament, is thicker and more cellular than usual.

The general pattern of the lesion was best seen in sections stained for myelin, and in fig. 7 transverse sections at several levels provide a general picture of the state of the cervical cord. This figure shows the gross reduction in size of the cord at the affected segments, *although the general configuration is preserved.* One naturally looks for evidence of pressure on the anterior or posterior surface of the cord, but in spite of the *obvious flattening* these aspects show relatively little demyelination.

In the 5th and 6th cervical segments *the demyelination is greatest* on the right side of the cord, where the striking feature is the degeneration in the lateral columns *spreading medially* from the attachment of the thickened denticulate ligament. There is also a prominent *area of demyelination in the anterior* part of the posterior columns. This unusual appearance is unlike a vascular lesion because it does not coincide with the territory of any vessel but is continuous across the posterior horn with the degenerated zone in the lateral column and with the denticulate ligament. Furthermore, the median septa are here shifted to the right, and, although this last may be partly an artefact, all these appearances together suggest that traction on the cord by the right denticulate ligament has played some part in the ætiology of the cord degeneration.

In the 7th cervical segment there is the same wedge of demyelination in the right lateral column as in the two segments above, and at this level also there is a similar relationship to the denticulate ligament. The demyelination in the posterior-root zones is particularly noticeable at this level. The cord at the 1st dorsal segment, below the lesion, is much more normal in size and appearance, but there is obvious descending degeneration in the right lateral column from the lesion above, and this could be traced through the lower dorsal and lumbar segments of the cord. In the upper cervical segments the cord also had a normal shape, and sections showed only ascending degeneration from the lesion below, which, however, in this case has led to a rather unusual appearance of the *posterior columns* (fig. 7). In each posterior column there are two areas of degeneration; the more medial, lying immediately adjacent to the median septum, *is secondary to the posterior-column destruction* at c5 and c6, whereas the more lateral band-like zone is a secondary ascending degeneration of the fibres of the

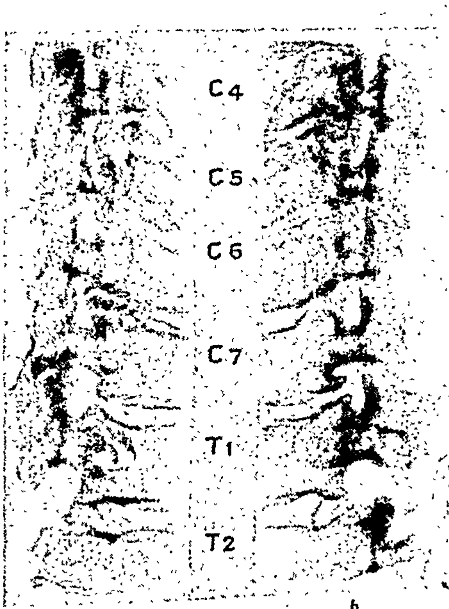

Fig. 3—Oblique radiographs of cervical spine (removed) to show intervertebral foramina.

th, 6th, and 7th cervical nerve-roots. Between this and e posterior horns the well-myelinated ascending fibres f the 3rd and 4th cervical nerves are seen. The great idth of the nerve-roots at entry and their rapid arrowing as they pass upwards are worth noting.

It is clear from these myelin-stained sections that ithin the cord there has been severe degeneration of the ntering nerve-roots in the most affected segments c5 and c6) and in the 7th segment, where at necropsy he left nerve had been seen to be stretched over a bony pur. *Outside the cord the roots of the 6th and 7th nerves* ere much thickened and degenerated, as is visible even n the myelin-stained sections (fig. 7). In these nerves here was a great increase in the collagen surrounding he individual nerve-fibres and an increase in the number of Schwann cells. There was also great variation in the size of the fibres and in the amount of myelin present. Lindblom and Rexed (1948) have described these changes more fully, and we agree with them that the patchiness of the degeneration is striking, some fasciculi being almost entirely degenerated, while neighbouring ones are comparatively unaltered.

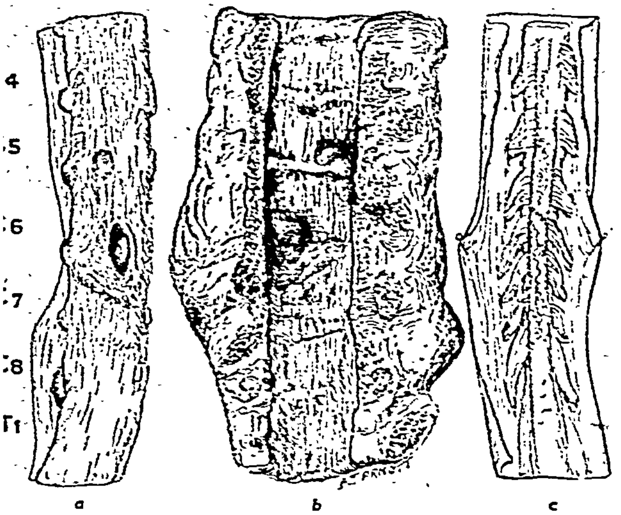

Fig. 4—Cervical spine and cord: *a*, cord and theca from in front after removal, showing site of dural adhesion and indentations of theca by protrusions; *b*, posterior aspect of vertebral bodies, showing the two main protrusions and line of dural adhesion; *c*, posterior aspect of cervical cord, showing wasting of segments 5–8.

It should be noted that the most severely degenerated segments of the cord were those at, and just rostral to, the dural adhesion, and that this was also the level at which the nerve-roots were most damaged. These findings suggest that traction on the cord by either or both these structures may have been an important factor in the ætiology of the condition.

The main spinal blood-vessels were patent. The veins on the dorsal surface of the cord, however, were prominent at the level of the lesion; hence it is possible that the vessels in the intervertebral foraminæ were compressed. Within the cord the walls of the vessels were thickened, and, as is usual, the thickening was most marked in the degenerated areas. The areas of degeneration did not correspond to the distribution of any of the major vessels; so it seems unlikely that ischæmia from vascular disease had played any great part in the pathology.

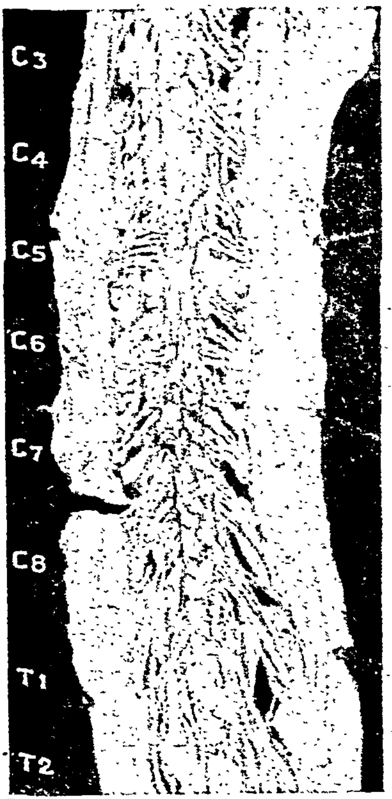

Fig. 5—Dorsal aspect of cervical cord, showing severe wasting most marked between segments 5 and 8.

DISCUSSION

The underlying disease in this case was that often called "osteo-arthritis of the spine"; the term spondylosis deformans, is, however, now generally accepted, and we have called it by this name. Schmorl showed that it was not an inflammation but a degeneration of the intervertebral discs with subsequent characteristic changes in the vertebræ, and it was he who devised the name spondylosis deformans as being more appropriate. Schmorl's work has been summarised in English in a monograph by Beadle (1931).

Cervical spondylosis has long been recognised as a factor in the development of brachial pain syndromes (Mettier and Capp 1941, Lund 1945, Philip 1950); and, as has already been mentioned, the occurrence of cord lesions in relation to cervical spondylosis is being given increasing attention by clinicians.

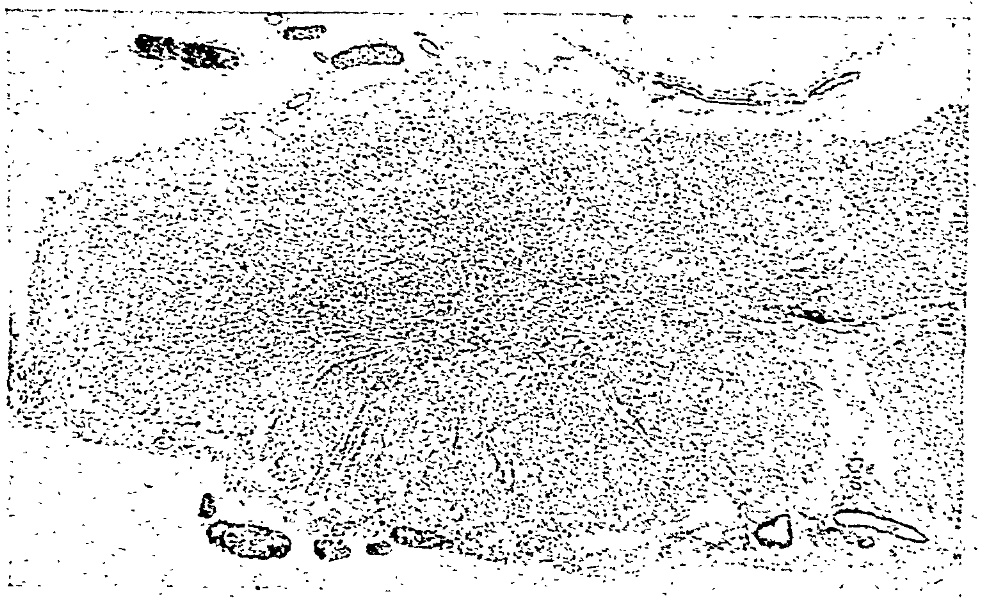

Fig. 6—Transverse section of right half of cord at C5.

Published reports of necropsy findings in these cases, however, seem to be very few.* In the case reported here an old woman slowly developed paralysis of her legs and weakness of her arms. During life the lesion was attributed to severe spondylotic changes in the cervical spine and at necropsy spinal-cord degeneration was found to involve at least three cervical segments (c5, 6, and 7) in close relation to the spondylotic lesions.

It is therefore reasonable to attribute, in some way, the progressive myelopathy to the spondylosis, but how the lesions are produced is uncertain. Here we may turn to the clinical observation that the spinal-cord signs recede in some of these cases if the neck is prevented from exercising its normal movements, which suggests that the cord may become vulnerable to normal neck movements. Further, Allen (1952) has observed, while operating on similar cases, that the spinal cord may blanch when the neck is flexed. The lesion usually develops gradually, and in our case at least there was no reason to inculpate the spinal-cord blood-vessels in the ætiology. A direct traumatic and self-inflicted lesion of the neurones is the most likely explanation, and this suggestion fits in well with the slowly developing characteristics generally observed. It should be emphasised, however, that not all cases showing this clinical syndrome are alike pathologically.

The microscopical sections from the present specimen suggested that the thickened denticulate ligament and the most degenerated nerve-roots were both closely related to the area of cord degeneration, and it seems likely that a tethering of these structures had played some part in the production of the myelopathy.

As regards treatment, the present case makes little contribution except to emphasise the difficulties involved in either surgical or conservative treatment of such a case. It may be possible safely to remove the bony spurs, as Allen (1952) advises, or the denticulate ligament may be divided, as suggested by Kahn (1947). Epstein and Davidoff (1951) strongly deprecated efforts to remove the bony ridges, owing to the danger of causing further cord damage. In this connection Allen (1952) emphasises the dangers of operating with full flexion of the neck and advises an extrathecal approach with a very cautious technique to avoid stretching the cord.

Fixation of the cervical spine by wearing a collar has proved its value in some cases. This, however, also presents difficulties, because long-continued fixation may cause osteoporosis, and most patients not only tire of wearing a collar sooner or later but also may be sceptical of treatment directed to the neck when their symptoms are in the legs. In some cases even a spinal fusion is worth considering.

It is evident, as the present case shows, that handling these patients presents many problems which are not yet fully solved.

SUMMARY

A case is reported (with post-mortem findings) in which there was degeneration of the spinal cord at the 5th, 6th, and 7th cervical segments in relation to cervical spondylosis.

It seems probable that abnormal fixation of the cord may render it vulnerable to normal neck movements. In

---

* Some cases have just been published by W. Russell Brain, Douglas Northfield, and Marcia Wilkinson (*Brain*, 1952, 75, 187).

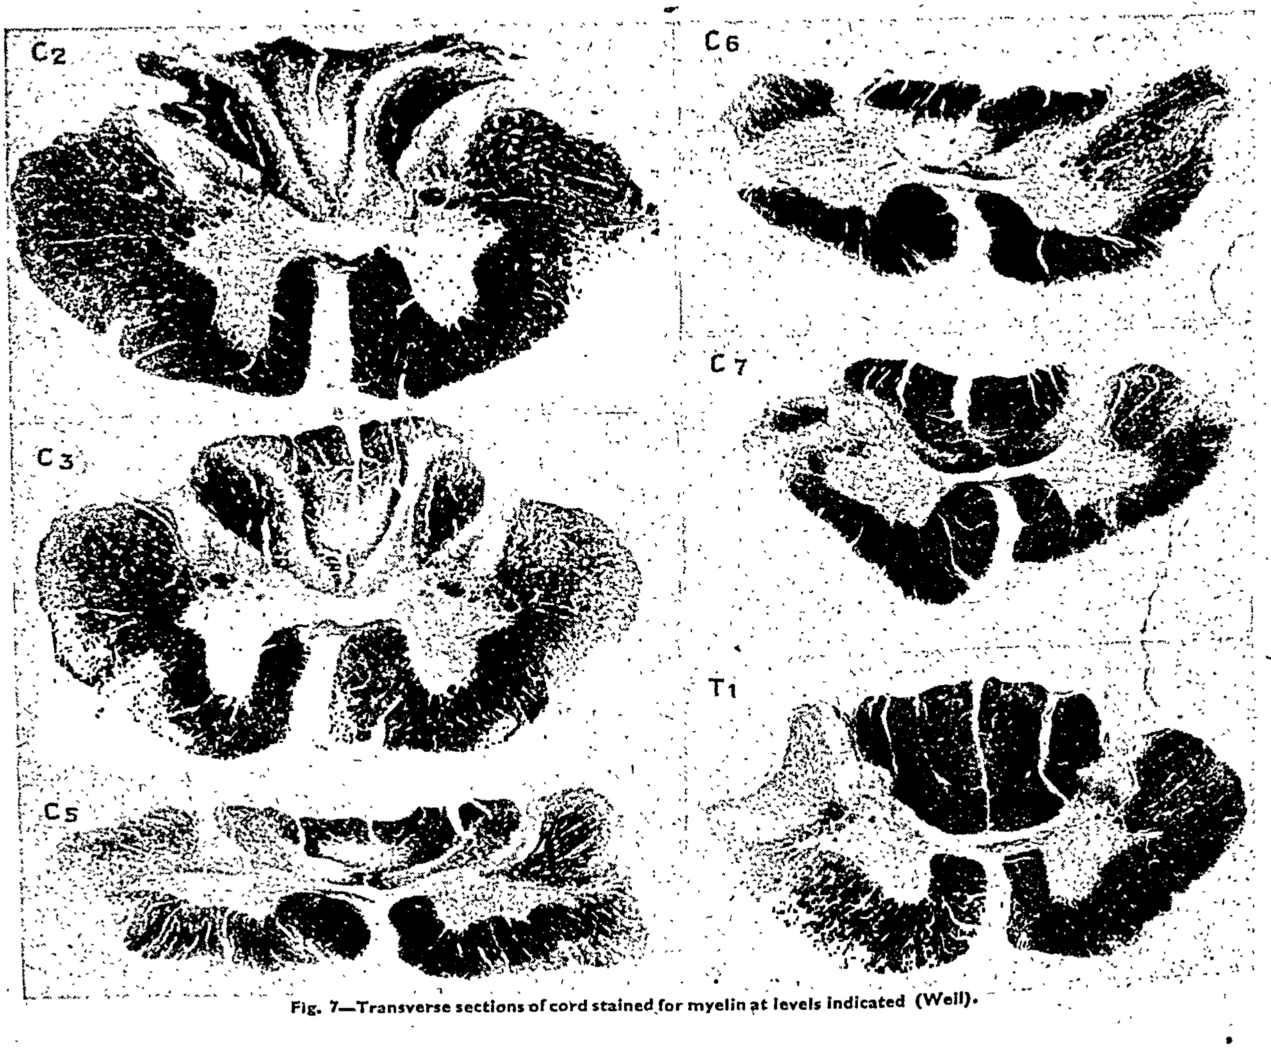

Fig. 7—Transverse sections of cord stained for myelin at levels indicated (Weil).

this case there was evidence of unusual tension on the thickened denticulate ligament and fibrous nerve-roots, and in addition the theca was adherent to the posterior longitudinal ligament. The ridges due to the spondylosis did not seem, per se, to have compressed the cord.

The implications for the treatment of these cases are discussed.

We particularly wish to thank Dr. J. G. Greenfield and Dr. Peter Daniel for all their help with this case, and Miss M. L. Prichard, D.PHIL., for the photomicrographs.

FRACTURES OF THE NECK OF THE FEMUR

A SIMPLE TECHNIQUE FOR THE INSERTION OF THE SMITH-PETERSEN NAIL

T. T. STAMM
M.B. Lond., F.R.C.S.
ORTHOPÆDIC SURGEON, GUY'S HOSPITAL, LONDON

ALTHOUGH internal fixation with a Smith-Petersen nail, or one of its modifications, is regarded as the standard method for treating a fracture of the neck of the femur, it should be considered primarily as a method of saving the life of the patient. It is often held that this injury kills elderly people because it confines them to bed. This is not true. Consider the thousands of bed-ridden old people in infirmaries. It is not being in bed that kills them, but being confined to bed *with pain*. Abolish the pain, and they will have the best chance of survival.

For this reason the primary indication for internal fixation is to relieve the pain. It is in fact a life-saving measure, which incidentally also offers a reasonable chance of obtaining union of the fracture.

Age and infirmity of the patient are therefore the most important indications for using this method, provided that the surgical manœuvres that it entails do not add too much additional risk.

The aim should therefore be to develop a method which causes the minimum of shock and disturbance to the patient, rather than one that will gratify the operator by its technical perfection.

At the outbreak of the late war, when all nursing-homes in London were temporarily closed, I was compelled to attempt the operation with the patient in his own bed. To my surprise, an ordinary single bed turned out to be an ideal operating-table for the purpose, and the operation was completed with the minimum of difficulty and very limited assistance. As a result of this experience, a technique of performing the operation without moving the patient from his bed was developed, and has now been used in over a hundred cases. It has proved to be so simple and satisfactory, and so few difficulties have been encountered, that I believe it merits a more general trial.

TECHNIQUE

The patient lies on his back in the centre of a standard hospital bed 3 ft. wide and remains in this position throughout. The operation can be performed in the patient's room or ward, or the bed may be wheeled into the operating-theatre. An X-ray cassette holder is slipped under the patient's buttocks; this is a flat wooden box, 15 in. square and 1 in. deep, open at one side so that the X-ray cassette can be slipped in for the anteroposterior view without disturbing the patient. It may be constructed from two pieces of plywood held 1 in. apart by slats on three sides.

Correct anæsthesia is important. It is necessary to have complete relaxation at the commencement but only for a very short time to allow the reduction to be accomplished easily and without trauma. After that, deep anæsthesia is unnecessary. The initial short and deep anæsthesia is obtained by the intravenous administration of sodium thiopentone 0·5 g. or less. The smallest dose that will be effective, given rapidly, is the ideal to be aimed at. Subsequent maintenance is with gas-and-oxygen, assisted by ether if necessary.

The surgeon "scrubs up" and arranges the sterile towels over the patient so that the affected leg is free though wrapped in a towel. Anæsthesia is not induced until this has been done. Thus the surgeon is ready to reduce the fracture while the patient is completely relaxed under the thiopentone; the limb does not have to be disturbed after reduction to put towels round it, and the pinning can be started immediately. With very nervous patients a screen may be used so that they do not see these signs of the coming operation.

Reduction is effected by the Leadbetter (1938) method: the knee and thigh are flexed to a right angle, and the thigh is then rotated externally and internally alternately, while upward traction is exerted with counter-pressure on the pelvis. This disimpacts the broken bone; and, when full internal rotation has been achieved, it is maintained while the thigh is brought down into a position of extension and abduction. The leg now hangs over the edge of the bed, and will be found to lie naturally in a position of full abduction and internal rotation. As the cassette holder compensates for the sag in the middle of the bed, the hip will also be in a position of full extension. Thus a constant and correct position for the leg is secured automatically.

A vertical incision 4 in. long is made on the outer side of the thigh, starting above at the level of the lowest part of the greater trochanter. The vastus lateralis muscle is split vertically, and two bone spikes are passed, one in front of and one behind the shaft of the femur, the handles being then separated to expose the bone. A blunt dissector is passed up along the bone deep to the muscle until it will go no further. This indicates that the dissector has reached the line of attachment of the muscle to the ridge on the lowest part of the trochanter, which provides a constant and easily identifiable landmark. At a point 1 in. below this level a hole $^3/_{16}$ in. in diameter is drilled through the cortex of the bone. If the fracture has been properly reduced, this hole will be in line with the centre of the inguinal ligament on the same side of the body and the anterior superior spine on the opposite side of the body. The point of a Watson-Jones calibrated guide (Watson-Jones 1936) is inserted into the hole and aimed in this line while being held horizontally. It is slowly pushed along through the bone until the increasing resistance of the head of the femur is felt.

Anteroposterior and lateral radiographs are now taken. For the lateral radiograph the cassette is wrapped in a sterile towel and propped up vertically at right angles to the inguinal ligament and with one edge resting against the iliac crest. The opposite leg is raised out of the way, and the X-ray tube is placed approximately where the knee of this leg lay on the bed. It is aimed so that the rays pass parallel to the inguinal ligament. The radiographs first of all check the reduction: if this is incomplete, which only happens very occasionally, the guide is partially withdrawn, the reduction is corrected by further manipulation, and the guide is pushed home again. Secondly, the radiographs check the position of the guide:

if this is incorrect, a second hole is drilled in the bone, and another guide is inserted before the first one is withdrawn. The desired length of nail is estimated from the position of the point of the guide and the calibration mark visible where the guide emerges from the bone, $^{1}/_{4}$ in. being allowed for impaction when the nail is driven home. The selected nail is threaded on to the guide wire, and oriented so that one fin points directly down the shaft of the femur, before it is hammered in. A further radiograph may then be taken, though this is usually unnecessary. In any event, the wound is closed while the X-ray film is being developed; this saves valuable time, and it is a simple matter to remove the stitches in the unlikely event of this being necessary.

ADVANTAGES OF THE METHOD

The chief advantages of this method are its extreme simplicity and the minimal degree of disturbance and shock to the patient. The only special instruments required are an ordinary Smith-Petersen set, consisting of a set of nails, cannulated for the Watson-Jones guide, two guides, cannulated punch, impactor, a bone drill, and, for peace of mind, a nail extractor. The operation can be performed anywhere, even in the patient's own bedroom, and the whole procedure does not take more than half an hour, including ten minutes for taking radiographs.

After some practice with this method it is justifiable to operate, if necessary, without radiographic control. I have done the operation several times without the aid of X rays, and the average time taken from the start of anæsthesia to the bandaging of the wound was twelve minutes. Although in such cases the nail may not be sited perfectly, it is almost impossible to miss the head of the femur, and it should always be possible to obtain fixation firm enough to relieve pain and make the patient comfortable.

DIFFICULTIES AND FAILURES

As in all surgical operations, difficulties and failures are occasionally encountered. Since some of these are avoidable, it may be of advantage to consider those that have been experienced, and the precautions now observed to guard against them.

Difficulty in Reducing the Fracture

Reduction may be difficult where the fracture is impacted or the operation is undertaken a long time after the accident. Impaction most commonly occurs in abduction fractures, and as a rule no attempt at reduction should be made. In late cases, where there is much upward displacement of the femur, a short preliminary period of traction is sometimes advisable. If the fracture is reduced during the stage of complete relaxation, which occurs immediately after the intravenous injection of sodium thiopentone, there will rarely be difficulty. In my experience incomplete reduction can usually be traced to a failure to secure and maintain full internal rotation of the femur.

Difficulty in Passing the Guide

The resistance to the passage of the guide should steadily increase until the articular surface of the head of the femur is reached. If the firm resistance of cortical bone is felt before the guide has been inserted for 3 in., it usually means that the guide has caught on the calcar femorale and must therefore be withdrawn and reinserted with a rather greater upward inclination.

Apart from this, difficulty in passing the guide is usually due to incorrect reduction of the fracture, and it is therefore better to check the reduction again by further manipulation rather than to continue trying to insert the guide in different directions.

Jamming of the Nail on the Guide Wire

This very trying accident is due to the nail catching on one of the grooved calibrations of a guide which is slightly bent. Unless the mishap is noticed, the guide will be carried in with the nail. While the nail is being hammered in, the punch should be withdrawn repeatedly to make sure that this is not happening. Guides can now be obtained which are calibrated without grooves, and this minimises the possibility of such an accident. It may still happen, however, if the guide is slightly out of true. If it happens, both guide and nail must be extracted together. Attempts to extract the guide only may lead to breaking off the portion extruding from the nail, which may then be left embedded somewhere in the joint.

Wrong Length of Nail

If a second guide has had to be inserted, and the length of nail required has been determined from the X-ray plate showing the first guide, a wrong length of nail may be selected. The only safe method is to feel the point of the guide impinge upon the cortical bone of the head of the femur, and to choose a nail a full $^{1}/_{4}$ in. shorter than the length shown on the guide where it emerges from the femur.

Loosening and Extrusion of the Nail

It is debatable whether any precautions should be taken to prevent the possibility of the nail being gradually extruded. If some of the bone in the neck of the femur is being absorbed, this extrusion may be beneficial; for it will prevent the nail from being protruded through the head of the femur into the joint cavity. On the whole, therefore, I prefer not to use any additional form of fixation of the nail.

Non-union

Though some cases of non-union must be expected, the technique described here helps to reduce this number to a minimum. First, the method of reduction and the position used encourage slight over-reduction of the fracture, thus impacting the upper margins of the fracture and rendering the fracture line more horizontal. Secondly, the method is so straightforward and simple that it is not necessary to transfix the head with several guide wires passing in different directions, a manœuvre which can do no good to the precarious blood-supply that remains to the upper fragment.

SUMMARY

A simple technique is described for the insertion of the Smith-Petersen nail for fractures of the neck of the femur, the essential feature being the use of the patient's own bed as the operating-table; in fact, the patient remains in his own bed throughout.

The method not only enables the operation to be performed anywhere without special apparatus, but also considerably reduces its length and also the disturbance and shock to the patient.

UNIVERSITY OF BRISTOL

MANY observers have reported that penicillin given by mouth in various doses, and at various intervals between doses, reduces the carrier-rate of hæmolytic streptococci and the incidence of acute throat infections in rheumatic children (Burke 1947, Maliner 1950, Maliner and Amsterdam 1947, Maliner et al. 1949, Goerner et al. 1947, Massell et al. 1948, Kohn et al. 1950, Pitt Evans 1950). Some of them have reported that the incidence of relapses of rheumatism was also reduced by penicillin; but this is a much more difficult matter to investigate, because relapses are not common, and it is difficult to secure comparable groups large enough to give convincing differences in incidence between those who have had penicillin and those who have not.

Brick et al. (1950) carried out a trial in Canada which was very similar to that described here. They treated 38 children attending a cardiac clinic as outpatients and observed a comparable but untreated group of 38 for two years. The treated children were each given penicillin 50,000 units by mouth half an hour before breakfast and the same dose three or four hours after supper. The children were examined once a month, and throat swabs were taken. In the penicillin group 570 swabs were examined, of which 3 were positive, and in the other group 576 were examined, of which 52 were positive. There were 3 recurrences in the penicillin group and 6 in the other.

METHOD OF PRESENT INVESTIGATION

There is in Bristol a comprehensive scheme for the care of children with rheumatism and heart-disease. The disease is notifiable, there is a supervisory clinic, and there are beds for long-stay cases at Winford Orthopædic Hospital and its annexe at Chew Stoke. It was at first intended to conduct the trial in two parts, one at Winford and the other in the outpatient department, but the number of children admitted to Winford became so small that it was impossible to divide them into large enough penicillin-treated and lactose-treated groups; so the inquiry was confined to children attending the supervisory clinic and some who were discharged from Winford while the experiment was going on. Ultimately 73 children were included in the trial. They were paired as far as possible in respect of sex, age, and date of last attack, and one of each pair was allotted to the penicillin and one to the lactose group by tossing a coin. This was done before the parents were asked if they were willing to help in the experiment.

When the parents were invited to take part they were not told to which group their child had been allocated, but unfortunately more of those allocated to the penicillin group accepted. Another difficulty in securing perfectly matched groups was that some of the children discharged from Winford lived too far from Bristol to attend the outpatient department regularly; and it so happened that there were more of these in the lactose than in the penicillin group.

For these reasons there were 41 children in the penicillin group and only 32 in the lactose group. In the penicillin group there were 27 girls and 14 boys, and in the lactose group 22 girls and 10 boys. The age-distribution (both sexes together) was as follows:

Year of birth	*Penicillin*	*Lactose*
1935–37	21 (*51%*)	16 (*50%*)
1938–40	12 (*29%*)	11 (*34%*)
1941–43	7 (*17%*)	4 (*13%*)
1944–45	1 (*2%*)	1 (*3%*)
Total	41	32

The most important factor in pairing was not appreciated at the beginning of the trial. This was the factor of an initial positive swab. Fortunately the distribution of positive swabs at the first visit was much the same in the two groups: 12 out of 41 (29%) in the penicillin group, and 10 out of 32 (31%) in the lactose group.

At the first visit to the outpatient department throat swabs were taken and the children in the penicillin group were given a fortnight's supply of tablets, each containing 200,000 units, and a bottle of 10% glucose solution (dose 2 teaspoonfuls). The children in the lactose group were given their tablets in a bottle exactly like that used for penicillin tablets and were also given the glucose. The children were usually asked to come up once a fortnight, but where there was some clinical indication they were asked to come in a week and an extra swab was taken. The throats of the children who started at Winford were swabbed once a week while they were in hospital and once a fortnight after discharge. Physical condition and erythrocyte-sedimentation rate (E.S.R.) were examined only where there was some clinical indication.

Throat swabs, which were taken by one of us, were taken to the laboratory and cultured with the minimum of delay—never more than three hours (usually less). They were plated on 5% horse blood-digest nutrient agar containing crystal-violet 1/700,000. The plates were incubated overnight in an anaerobic jar. β-hæmolytic colonies were subcultured on blood-agar and the resulting pure cultures grouped by the method of Maxted (1948). All cultures found to be of Lancefield group A were then sent for typing to the Streptococcal Reference Laboratory at Colindale. They were first tested by the slide agglutination method and subsequently by the precipitin method. Throughout the trial the penicillin sensitivity of the group-A streptococci isolated was determined by comparison with the Oxford staphylococcus on penicillin ditch plates (5 units per ml.). All were at least as sensitive as the control organism.

The children came into the trial at slightly different times, but most of them attended from the middle or end of October, 1950, to the middle or end of May, 1951. There were defaulters both in respect of individual visits and because some of the children started work and could no longer attend regularly. These failures to attend seriously impaired the tidiness of the trial, and the possibility of excluding some of the irregular attenders from the final comparison was considered. It was felt, however, that it would be better to set out the results in such a way that irregularities of attendance were obvious, and this has been done in the accompanying figure. As the children were attending as outpatients, it was necessary to rely on them and their mothers to ensure that they actually took the tablets given.

The average number of swabs taken per child was slightly larger in the penicillin group (14·6) than in the lactose group (12·6) because there were more Winford children in the penicillin group. Swabs were taken once a week while they were in hospital, but only once a fortnight when they became outpatients.

RESULTS

The results of the trial are summarised in the accompanying table. Those in section A are the children in whom treatment had either no effect or possibly some preventive effect; those in section B are those in whom treatment appeared to produce a definite improvement; and those in section C are the "failures."

In the penicillin group 18 (44%) out of 41 children, and in the lactose group 22 (69%) out of 32, had a

RESULTS OF INVESTIGATION

	First	Later	Penicillin	Lactose
A	0	All 0	23 (*56%*)	10 (*31%*)
B	+	All 0	8 (*20%*)	1 (*3%*)
C	0	Some +	6 (*24%*)	12 (*66%*)
	+	Some +	4	9
Total			41	32

positive swab at the first visit or at least one positive swab later. The accompanying figure shows the sequence of events in these 40 children. In a few cases *hæmolytic streptococci* of group C were isolated, and this has been indicated by a C in the figure. It is generally held that these organisms are of no significance in acute rheumatism; so the Cs have been counted as Os in the totals in the columns on the right of the figure.

The effect of the penicillin in reducing the number of positives in the group as a whole is obvious, but some of the individual records are also of interest.

Penicillin Group

Six children (nos. 8, 9, 11, 14, 15, and 16) had a negative swab at the first visit and subsequently had at least one positive. Nos. 9, 14, 15, and 16 had only one positive without symptoms, whereas nos. 8 and 11 had three each, and both had a sore throat.

No. 8 started treatment on Oct. 23. She seemed perfectly well and had negative swabs on Oct. 23 and Nov. 6. On Nov. 12 she went to bed for two days with a sore throat. On Nov. 20 she seemed quite recovered and she had a negative swab on that day, on Nov. 27, and on Dec. 4. On Dec. 18 she had a small sore at the angle of the mouth and a strongly positive throat swab. On Jan. 3, 17, and 29 her swabs were negative, but on Feb. 12 and 26 they were positive. After that her swabs were consistently negative. Unfortunately the culture from the swab taken on Dec. 18 died out and could not be typed, but the hæmolytic streptococci cultured from the swabs on Feb. 12 and 26 were of the same types.

No. 11 started treatment on Oct. 25. She was seen on Oct. 25 and Nov. 8 and 29, when she seemed perfectly well and had negative swabs. On Dec. 9 she went to bed with a sore throat and was seen at home on Dec. 14. Her throat was then a little injected, but she seemed to have nearly recovered, and a swab was negative. She was seen again, as an outpatient, on Dec. 19, when she seemed well, her E.S.R. was 3 mm. in 1 hour, and a swab was negative. On Jan. 9 and 24 she seemed perfectly well but had positive swabs. On Feb. 7 she had a negative swab, on Feb. 21 another positive, and after that her swabs were consistently negative. The hæmolytic streptococci cultured from swabs taken on Jan. 9 and 24 and on Feb. 21 were all of the same type.

Nos. 2, 3, 5, and 6 had a positive swab at the first visit and at least one positive at a later visit. Nos. 2 and 3 had only one positive at a visit other than the first, and neither of them had a sore throat. In both cases the type of streptococcus was the same in the first and later swabs. Nos. 5 and 6 were so irregular in attendance that it seems doubtful whether they should be included in the penicillin group at all. Between them they supplied eight of the twenty positive swabs recorded for the whole group at visits other than the first.

Lactose Group

Most of the positive swabs came from chronic carriers, and it seems reasonable to suppose that some of those in the penicillin group who had positive swabs at the first visit would have been chronic carriers if they had not been treated. There was nothing in the appearance of the throats of the chronic carriers to distinguish them from the other children.

Nos. 23, 27, 32, 33, and 37 gave a series of positive swabs after a series of negative ones.

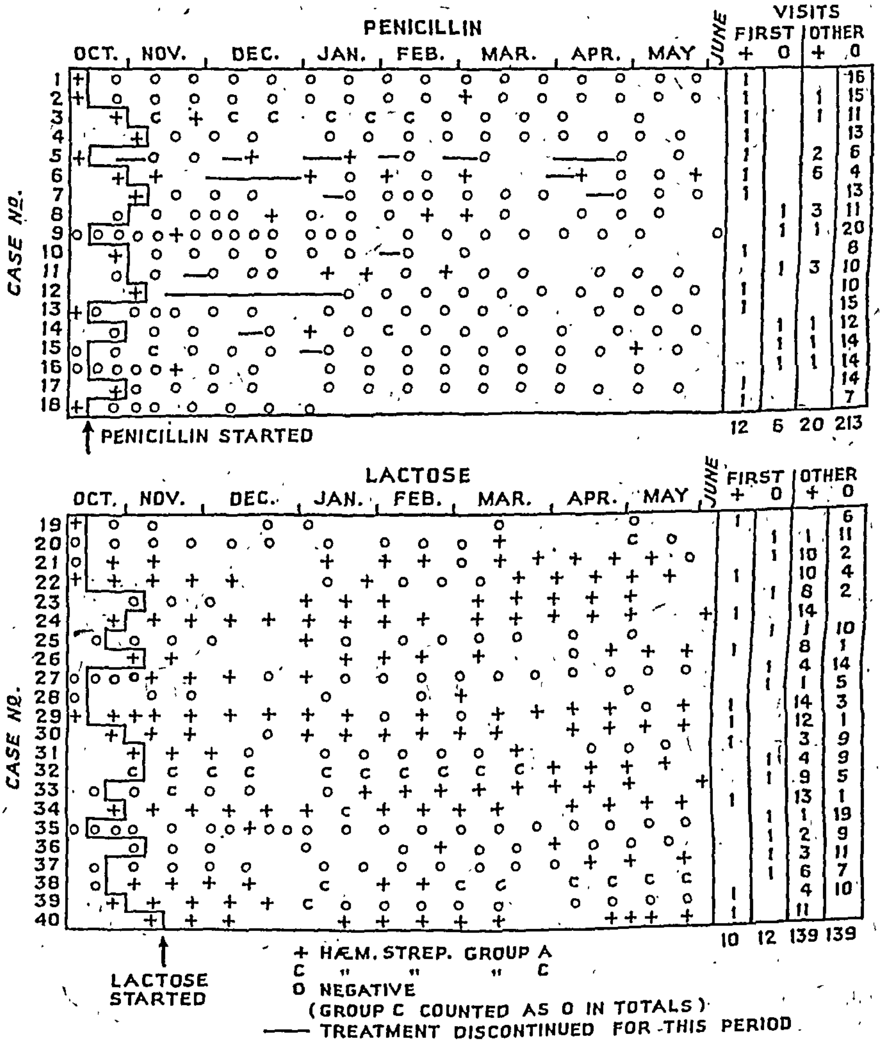
No. 23 had negative swabs on Nov. 1, 15, and 29. About Dec. 13 she had a sore throat and was in bed for three days. On Jan. 3 she seemed well but had a positive swab and later swabs were consistently positive.

No. 27 had negative swabs on Oct. 13, 20, and 27, and Nov. 3. He was discharged from Winford on Nov. 5 and when seen as an outpatient on Nov. 8 he gave a positive swab. Swabs on Nov. 22, Dec. 6, and Jan. 3 were all positive, but one on Dec. 20 was negative. All his swabs after Jan. 3 were negative.

No. 32 had consistently negative swabs till April 17, when they became consistently positive.

No. 33 had consistently negative swabs up to Jan. 22, when they became consistently positive. After the trial she complained of sore throat and painful glands in the neck (June 19), and on July 19 she was admitted to hospital with a slight recurrence of chorea.

No. 37 had consistently negative swabs up to and including April 2. On April 13 she had malaise but no sore throat and



Results in children who had positive swabs at the first or a subsequent visit.

was in bed for a few days at home. On April 18 she seemed well but had a positive swab on that day and on May 2. About May 9 she developed pain and swelling in the left knee, and was admitted to hospital on May 17 with a slight relapse. She had further positive swabs on May 21 and June 7.

It would clearly have been desirable to attempt a comparison between the incidence of sore throats in the penicillin and lactose groups, but in an investigation of outpatients it is impossible to define a sore throat with sufficient precision to give useful comparisons.

None of the children reported any ill effects from the penicillin, and none of the streptococci of group A isolated were resistant to penicillin.

DISCUSSION

This investigation confirms previous work in showing that a daily dose of penicillin by mouth will very considerably reduce the number of throat swabs positive for group-A hæmolytic streptococci in rheumatic children. It leaves unanswered two questions which are more important from the practical point of view: (1) does oral penicillin prevent relapses? and (2) does it prevent acute infections? It is difficult to see how the first question could be answered in a reasonable time with numbers of children of the order available in this investigation. The second question is difficult to answer by an experiment on outpatients. It seems certain, however, that oral penicillin is not a sure preventive of mild throat infections, because at least 2 of the penicillin group (nos. 8 and 11) had them.

SUMMARY

A group of 73 rheumatic children was observed at fortnightly intervals in an outpatient department from October, 1950, to May, 1951. 41 children were given a daily dose of 200,000 units of penicillin with 10% glucose before breakfast, and 32 were given lactose and glucose.

The number of throat swabs positive for group-A hæmolytic streptococci obtained from the penicillin group was very much less than the number obtained from the lactose group.

No conclusive evidence was obtained about the effect of the penicillin in preventing either rheumatic relapses or acute streptococcal throat infections. Only 2 children, both in the lactose group, had rheumatic relapses.

NOTE ON RESULTS OF TYPING

In the lactose group there were 17 children who had more than one positive swab. In 9 of those children the organism was of the same type in every positive swab, in 2 there was a definite change of type, and in the remaining 6 there was some doubt because some swabs produced several types.

In the penicillin group there were 6 children who had more than one positive swab. In 5 of them the organism was of the same type in every positive swab, and in 1 (no. 5) there was a definite change of type. The child who had a definite change of type was irregular in attendance.

We are indebted to Mr. L. J. Waller for much technical assistance; to Dr. R. E. O. Williams and his co-workers at Colindale for the typing; and to Prof. R. H. Parry, medical officer of health for Bristol. The trial was made possible by a grant from the Royal College of Physicians (Miss H. A. M. Thompson bequest).

ECTOPIC PREGNANCY INSIDE THE UTERINE WALL IN A FIBROMATOUS UTERUS

L. ACHMATOWICZ
M.D. Warsaw
SURGEON, LAUTOKA HOSPITAL, FIJI ISLANDS

THE following case is worth recording because of its rarity.

CASE-RECORD

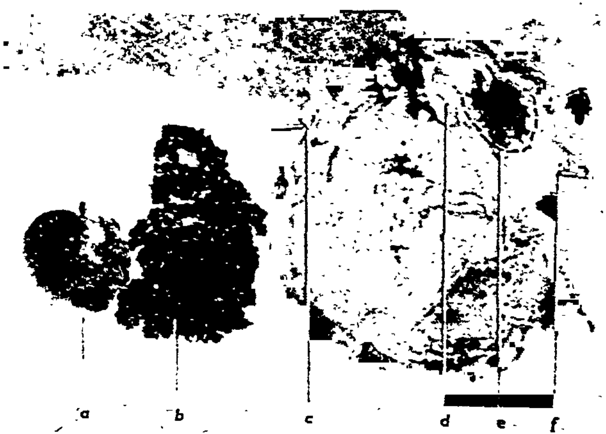
On Oct. 15, 1951, a European woman, aged 41, was admitted to hospital with what appeared to be a ruptured ectopic pregnancy. That day, while having lunch, she had suddenly felt an extremely sharp pain in the umbilical region and left shoulder, and had felt as if "a sharp knife had been pushed into her vagina"; she fell down on the floor, but did not lose consciousness. She had vomited at home twice, and four times on the 75-mile ambulance journey to hospital. Micturition and defæcation were normal. She had menstruated in August, when her period began on Aug. 3, lasted only three days, and was very scanty. In September and October she had menstruated at normal intervals, but only one day on each occasion, and very little.

Past History

She began to menstruate at 12, the menstrual cycle being 8/28 days, and bleeding heavy. At the age of 16 she underwent appendicectomy. At 28 she married, and she conceived soon afterwards. At the time of the first suppressed period she had extremely severe lower abdominal pain and laparotomy was done under spinal anæsthesia. When the abdomen was opened, she heard the surgeon say "she is pregnant," and the abdomen was closed. She subsequently miscarried a $5^1/_2$ month fœtus. After this, her periods became heavier, and each time she lost much blood. Fibromatosis of the uterus was diagnosed, and in 1939 a myomectomy was done, several fibroids being removed. In spite of this operation abdominal pain and distension persisted, and though she became pregnant in 1940 she aborted at 3 months. In 1941, however, she was delivered of a healthy girl. During her pregnancy she had severe hæmaturia every 28 days, lasting 8 days, which coincided with her suppressed menstrual period. Her urine had the same odour and consistence as the menstrual flow, and she "felt very weak."

Immediately after the birth of the baby the periodical hæmaturia disappeared. After $3^1/_4$ years, in 1944, she again became pregnant, and again had periodical hæmaturia. At cystoscopy the bladder appeared to be normal. The hæmaturia was attributed to an anterior low attachment of the placenta and adhesions between the uterus and the bladder. A girl was born at term, and the hæmaturia disappeared immediately after.

The next pregnancy, in 1945, terminated in abortion at 3 months. During this pregnancy, the patient again had periodic hæmaturia, which ceased after abortion.



Posterior view of uterus: *a*, fœtus; *b*, chorionic villi; *c*, pin in left fallopian tube; *d*, fibroma; *e*, opening into gestation cavity; *f*, pin in right fallopian tube.

On Examination

The patient was pale, with temperature 97·8°F, and pulse-rate 84. Her abdomen was slightly distended, very rigid, and extremely tender, especially in the right groin and in the area of McBurney's point. A large oval smooth soft mass could be felt in the right iliac fossa. Vaginal examination revealed no bleeding. The uterus was enlarged to the size of a grape-fruit, soft, and tender, and there was tenderness in both lateral fornices.

Treatment and Progress

As the patient's condition was still satisfactory after her long trip in an ambulance on a rough rubble road, it seemed probable that, if she had a ruptured ectopic pregnancy, the bleeding had stopped. Anti-shock treatment was applied, and the patient observed throughout the night. Next morning her general condition was satisfactory, and she had slept well, but was nauseated and had vomited small amounts several times. Her temperature was 98·4°F, her pulse-rate 90, and a blood-count showed red cells 2,200,000 per c.mm., Hb 32%, white cells 9500 per c.mm. At 11 A.M. her pulse-rate was 100. A ruptured ectopic pregnancy, probably in the right tube, was diagnosed.

Operation

Laparotomy was performed under general anæsthesia at 2.30 P.M. A blood-transfusion of $1^1/_2$ pints was given. On opening the abdomen through a midline incision, clotted and fluid blood was found, especially in the right half of the pelvic cavity. Old dense adhesions covered both appendages and the uterus, and multiple adhesions connected the omentum intestines, and uterus. These were cut and tied off to free the reproductive organs. The uterus, which was as big as two fists, occupied the middle part of the pelvic cavity. No ectopic pregnancy was found in the appendages, but on the posterior wall of the uterus, near the base of the fundus, among dense adhesions, which had at first limited the bleeding from the tear, an opening, 0·5–1·0 c.m. across, was found into which chorionic villi and a shining ovum were protruding. When this aperture was palpated it suddenly became larger, and first the ovum, and then the placenta, prolapsed. As soon as this happened, profuse hæmorrhage took place, which was controlled. In view of the extremely long history of the case, and the present rupture of the uterus, a supracervical hysterectomy was done. The postoperative course was uneventful.

Pathology

The uterus contained several small subperitoneal and intramural fibromata. Old dense adhesions covered its posterior and anterior surfaces, especially at the fundus. Just off centre in the right side of the posterior surface of the fundus, among adhesions, there was a tear in the wall of the uterus about 2·5 cm. in diameter. The left flap of the torn wall was everted medially, and a fibroid as big as a pea was embedded in it. The torn opening in the wall of the uterus led to a cavity 4·5 cm. deep and 2·5 cm. wide containing a fœtus and chorionic villi; it was not lined with decidua. Only a few decidual cells were attached in a corner to the chorionic villi (verified microscopically), and this cavity was separated from the uterine cavity by an intact muscular wall 4 mm. thick. No connection of any kind could be found between these two cavities. The intra-uterine parts of both tubes were separated from the gestation cavity by an intact muscular wall 1·5 cm. thick on the right side and 3·5 cm. thick on the left. The tubes were apparently healthy. The uterine cavity was lined with decidua vera.

DISCUSSION

In discussing the mechanism of this ectopic gestation several possibilities must be considered.

(1) The ovum may have been fertilised and implanted in a mucous crypt inside the uterine wall, or in a diverticulum from the uterine cavity. This is improbable, since the gestation cavity was not lined with decidua, and only a few decidual cells were found in a corner attached to the chorionic villi. In addition, the wall which separated the gestation cavity from the uterine cavity was 4 mm. thick, and there was no connection between them.

(2) The possibility of implantation of the ovum in the intra-uterine portion of the right or left tube, with further expansion into the uterine wall, and subsequent rupture, must be discarded because the interstitial portion of the left tube was separated by intact uterine muscle 3·5 cm. thick, and the right tube by intact uterine wall 1·5 cm. thick.

(3) The third possibility is that the ovum, on its external migration after fertilisation, became implanted on the posterior surface of the uterus, possibly where the epithelium had been damaged by fibromatosis or by dense adhesions. In the further course of its development the ovum burrowed into the uterine wall and, after nearly three months growth, ruptured into the abdominal cavity.

This last mechanism appears the most probable.

I wish to thank Dr. J. M. Cruickshank, Director of Medical Services, Fiji, for permission to publish, and Dr. P. E. C. Manson-Bahr, acting pathologist, for the histological examination.

AN OUTBREAK DUE TO SALMONELLA BRANCASTER

E. HINDEN
M.D. Camb., M.R.C.P.
PÆDIATRICIAN TO WHIPPS CROSS HOSPITAL, LONDON

JOAN TAYLOR
M.B. Lond., D.P.H.
SALMONELLA REFERENCE LABORATORY, COLINDALE, LONDON

W. W. WALTHER
M.B. Lond.
AREA PATHOLOGIST, WHIPPS CROSS HOSPITAL, LONDON

Salmonella brancaster was first described by Macdonald et al. (1948); it had been discovered in mussels. Subsequently a second strain was isolated from the liver of a dead turkey poult. Although this organism has been found in the stools of a healthy person (Ministry of Health 1951) it has not hitherto been described as a cause of disease in man. An outbreak caused by *S. brancaster* in a children's ward is therefore considered worthy of record.

The organism was isolated, almost simultaneously, from two widely separated sources in the hospital. The first was an infant (case 1 in the accompanying table), an "unidentified salmonella" being grown from a stool passed on Jan. 17, 1951. The second source was an old lady who died on Jan. 19 from "senile myocardial degeneration"; a culture taken from her spleen because it was unaccountably enlarged and soft grew a salmonella. Both cultures were sent to the Salmonella Reference Laboratory and identified as *S. brancaster*.

The ward where the outbreak occurred was used mainly for bottle-fed babies; most of them were aged less than 12 months, but babies were accepted up to the age of 18 months. The ward consisted of a long corridor along one wall, with cubicles and the kitchen opening to it from the other side; on the wall side opened the sluices, bathroom, and sterilising-room. There were 12 cubicles, arranged 6 on each side of the kitchen, which was fitted out as a milk-kitchen also. One of the 12 cubicles was used as the sister's office; the others each held two cots, but often one of a pair could not be used because an infectious patient was in the other. This gave a theoretical capacity of 22, but in practice at least 3 or 4 cubicles were used for infectious diseases, giving a practical maximum of 18 or 19 infants. January was not very busy, but February and March made very heavy demands on our accommodation, and there were often 18 babies in the ward.

The outbreak occurred in two clearly defined periods. The first report of *S. brancaster* in an infant's stool was returned on Jan. 19; positives were often found from then till Feb. 6. This we call "the first positive period." Thereafter the organism could not be found at all in the ward for a fortnight—"the negative period." It was isolated again on Feb. 18, and thereafter was constantly found till the ward was evacuated on April 17—"the second positive period."

On Jan. 19 there were 9 children in the ward, 4 of whom ultimately became infected; the other 5 remained clear. All of these latter left soon after, within the first positive period. Of the infected children, 2 left fairly soon; but the other 2 remained in hospital right through the negative period into the second positive period. Thus they may have carried the infection and later restarted it; but each had had at least 3 negative stool-tests. A further 21 children were admitted during this first positive period, but none of them caught the infection. Only 2 of these stayed on through the negative period, and may conceivably have become symptomless carriers. During the negative period 25 infants were admitted; 2 of these later contracted the infection. During the second positive period 25 children came into hospital, and 4 of them became infected. Admissions were reduced during March; only 5 patients were admitted after March 5, and the ward was closed to further patients on March 18.

The table gives the clinical details of the 10 infected babies.

In the first period 4 babies were involved, 2 of whom had mild diarrhœa without constitutional symptoms; the other 2, in no way disturbed, were found on a search through the ward. The last positive stool of this group was passed on Feb. 5. In the second period 6 babies were infected. All of them showed gastro-intestinal upset, and 2 required parenteral fluids. We had the impression that the infection picked out the seriously ill infants in the ward.

From 5 of the 6 babies concerned in the second period of the outbreak sera were obtained and investigated for the presence of agglutinins to *S. brancaster*. These results also are shown in the table. No significance can be attached to the results from cases 6, 9, and 10. Case 7 showed a fall in titre of 'H' agglutinins between 7 and 22 days after the onset of diarrhœa. Case 8 showed significantly high titres to both 'O' and 'H' agglutinins 7 days after onset, these titres dropping to less than 1:25 after a further 14 days. This drop confirms the diagnosis of infection with *S. brancaster*.

Only 3 nurses were found to be infected:

Nurse A, whose stools were negative on March 24, was found to be passing the organism on April 14. She had no symptoms, and the next three stools were all negative.

Nurse B, who made no complaint and had no symptoms, was found to be passing *Shigella sonnei* in her stools on March 28 and 31; on the latter date *S. brancaster* also was recovered. This organism was subsequently grown on April 14, but the next three stools were negative.

Nurse C was the only one who complained of diarrhœa, and her stools grew *S. brancaster* on one occasion only, April 5.

BACTERIOLOGY

The routine method used at the Whipps Cross Hospital Area Laboratory to isolate salmonellæ from outbreaks of food-poisoning is to make primary cultures of stools or rectal swabs on desoxycholate-citrate agar in a petri dish and on selenite-F broth. Next morning the selenite-F broth-culture is subcultured on to desoxycholate-citrate agar, and the original culture on this medium is examined. Probable pathogens are tested by slide agglutination and subcultured into the fluid carbohydrate media to test their metabolic activity.

S. brancaster grew well on primary culture on desoxycholate-citrate agar, and it was seldom necessary to subculture from the selenite-F broth. The appearance of the 18-hour colony on desoxycholate-citrate agar was characteristic. It was larger (1·5–2·5 mm. in diameter) than, for example, a typical *S. typhimurium* colony, and it showed a faint greenish opacity in the centre. All the colonies were smooth. The biochemical reactions were typical of members of the salmonella group. The organism was slightly sensitive to streptomycin, and fully sensitive to chloramphenicol and aureomycin. By slide agglutination, the organism was agglutinated by standard *S. paratyphi-A* 'O' and *B* 'O' sera, and less actively by *S. typhi* 'O.' None of the 'H' sera in stock agglutinated it. Detailed serological analysis showed that the somatic structure of this organism may be expressed by the symbols I.IV.XII. The somatic structure of *S. paratyphi-A* 'O' is I.II.XII. and of *S. typhi* 'O' is

* Titre expressed as reciprocal. —, no agglutination at a titre of 25. "Clear" means that three consecutive stools were negative.

IX.XII. The agglutination observed in sera made from these two organisms is due to the agglutination of antigens common to all three organisms. The somatic structure of *S. paratyphi-B* 'O' is (I).IV.(V).XII., the factors in parentheses being absent from some strains. The somatic structure of *S. brancaster* is identical with that of some strains of *S. paratyphi-B*. The flagellar phase of *S. brancaster* isolated in this outbreak was identified as z_{20}; hence the complete antigenic structure was I.IV.XII : z_{20}.

INVESTIGATION OF SPREAD OF INFECTION

Our efforts to trace the spread of infection followed two main lines: (1) investigation of possible human carriers, and (2) investigation of possible contamination in the ward—e.g., dust, bedsteads, furniture, walls, milk-bottles, and teats.

(1) Doctors, nurses, and ward orderlies, particularly those who had had any contact with the ward in which the old lady had been, were investigated. Fæces or rectal swabs were examined, and serum was sent to the Reference Laboratory for examination for the presence of specific antibodies, but these investigations proved negative except for the 3 nurses mentioned above. Attempts were made to detect agglutinins in the sera from nurses and ward orderlies. Of the 3 infected nurses, only one serum showed the 'O' agglutination to a titre of 1 : 25. Sera from a further 41 nurses were examined; only one agglutinated the 'H' phase of *S. brancaster* at 1 : 25. Sera from 14 ward orderlies were examined, none of which agglutinated *S. brancaster* 'O' or 'H.'

(2) Swabs were taken of brooms and various parts of cots, furniture, and walls within reach of infants occupying the cots, but all these gave negative results. The milk-bottles and teats were boiled before use and found always to be sterile.

Finally, the general antiseptic technique was reconsidered, and 1 : 80 'Lysol' solution was substituted for the weak 'Dettol' solution used in cleaning cots and furniture. After this change no further cases were discovered. It was interesting to compare dettol with phenol by the Rideal-Walker technique, using *S. brancaster* as the test organism instead of *S. typhi*. The phenol coefficient of dettol in distilled water was then found to be 1. When plasma was used as diluent, the coefficient was reduced to 0·075, and when broth was used, to 0·03.

SUMMARY

An outbreak of *Salmonella brancaster* infection in an infants' ward is described.

The infection occurred in two periods with a free interval between them and affected 10 infants.

The clinical picture varied from no gastro-intestinal symptoms to severe enteritis. All the patients recovered, but some babies continued to excrete the organism for several months.

Three nurses also were infected, only one of whom had mild diarrhœa.

About the time that the outbreak started *S. brancaster* was also found post mortem in the spleen of an elderly patient who had died (in a ward remote from the babies) from senile myocardial degeneration. In spite of a careful search no connection could be traced.

It is a pleasure to acknowledge the great help we have received from our colleagues, both medical and auxiliary, in the work of investigating and controlling the outbreak. In particular we wish to thank Sister M. Kent and Mr. Kenneth Podger, laboratory technician, both of Whipps Cross; and Mr. Douglas Miller, technical assistant, of the Salmonella Reference Laboratory.

LOSS AND RECOVERY OF SIGHT IN MEASLES ENCEPHALITIS

G. H. JENNINGS
M.A., M.D. Camb., F.R.C.P.
SENIOR PHYSICIAN, EDGWARE GENERAL HOSPITAL, MIDDLESEX

MEASLES encephalomyelitis occurs, if the figures of the large epidemics of measles are a guide, once in about every 1000–1500 cases during an epidemic (Boehnheim 1925, Peterman and Fox 1933, Hoyne 1939, Geiger and Sappington 1940, Litvak 1947). It seems to be more likely to occur at the peak of an epidemic (Peterman and Fox 1933, Roisman and Rosen 1943) and, conversely, to be less common among sporadic cases; 8 cases in the London epidemic of 1936 were mentioned in the *British Medical Journal* (1936).

The drowsiness, vomiting, convulsions, and meningitic signs which accompany measles encephalitis are unlikely to be overlooked, particularly since they often come on suddenly on the fourth or fifth day after the appearance of the measles rash and after initial improvement in the patient's condition; some cases show predominant cord signs—e.g., paraplegia and ascending paralysis. In either type of the illness the course may be brief or long, but if death takes place it is usually early and may be on the first day in fulminating cases. Zimmerman and Yannet (1930) have computed that 10% of all measles encephalomyelitics die, and that 65% show a final residual mental impairment.

Litvak et al. (1943) suggest that there is no relationship between the severity of the measles and the incidence of encephalitis, or between the severity of the encephalitis and the liability to residual nervous lesions. They suggest that the longer the cases are followed the more noticeable are mental and personality disorders and the less become the neurological findings (cf. Neal and Appelbaum 1927).

The chief pathological lesions are focal perivascular demyelination and diffuse congestion of the brain (Greenfield 1929). One particular focus of demyelination is in the optic nerves with resultant blindness. This rare symptom is generally transient, as appears not only from the case described here but also from those cited by Ford (1928), Hamilton and Hanna (1941), Litvak et al. (1943), and Meurer (1948).

The present case was seen during a measles epidemic in which the weekly notification for the previous month in England and Wales lay between 17,300 and just over 20,000 cases. This occurrence just after the peak of an outbreak has been generally observed in measles encephalitis and suggests the likelihood that the measles virus is causal and not merely an associated neurotropic virus.

CASE-RECORD

A boy, aged 7½ years, developed a typical measles rash on March 16, 1949, after two days' prodromal symptoms. After a further two days the rash began to fade and the child felt better and sat up in bed, but on March 19 he was listless and drowsy, and again without appetite. No further symptoms appeared, but he became more drowsy, and on March 21 he was incontinent of urine.

On examination by me on March 23 he was very drowsy but rousable into coöperation and not appreciably disoriented. His optic discs were clear but showed slight overfilling of the veins. He had severe neck stiffness, a positive Kernig's sign, and severe general spasticity in all four limbs, more especially in the arms, which also showed slight intention tremor. The tendon-jerks were all very brisk; the abdominal reflexes were absent, and the plantar reflexes flexor. The boy was afebrile, but a fading measles rash was still present.

Lumbar puncture showed clear cerebrospinal fluid (C.S.F.) under a pressure of 50 mm. and containing protein 100 mg. per 100 ml. but no increase in cells.

Progress.—Next day (March 24) the boy was much worse; he was flushed and slightly cyanotic, with temperature

THE 89

99·8°F, respirations 36 a minute and shallow. He was unrousable, with eyes closed and expressionless face. His limbs showed severe though varying spasticity, particularly in the arms, which also showed attacks of convulsive shaking lasting one or two minutes. During the next two weeks the patient lay speechless and inert, but in the second week he was more irritable and grumbled at times. From March 30 there were spasms of the facial muscles and at times fine nystagmoid jerkings of the eyes. Meningitic signs persisted, and there was constant spasticity with increased response in the limbs and jaw reflexes, particularly in the right arm. The right plantar reflex was now extensor. Muscle power could not be tested, but when requested the patient could partly protrude his tongue. A grasp reflex was present till April 14. A small area of consolidation appeared at the base of the right lung on April 3 and cleared with sulphonamide therapy. The patient took fluids and light solids satisfactorily by mouth.

Lumbar puncture on April 7 produced clear C.S.F. under a pressure of 100 mm. and containing protein 50 mg. per 100 ml. and no increase in cells. A Pandy test was faintly positive.

Further Progress.—From April 11 though still drowsy and incontinent, the patient gradually became mentally receptive and smiled faintly if amused. He ceased to whine on April 16 and was fully rational, though speech remained distant and monotonous. There was possibly a slight intention tremor of his arms, which he often moved aimlessly through the air. On April 19 he could only dimly discern the white coat of the doctor by his bed, and the outer halves of his optic discs were white; his pupils reacted imperfectly to light. His legs, though wasted, showed fair power, and the other nervous signs were little changed, with persisting constipation and urinary incontinence.

Examination of Eyes.—Mr. J. Gibson Moore reported on April 22: “ Early optic atrophy R. and L., L. more advanced. Pupils sluggish, but react to light. Ocular-movements full.”

Recovery.—The patient’s conversation became quite sensible by May 4, and despite poor vision, especially in the left eye, he was bright and cheerful. His optic discs remained very pale and tendon-jerks much increased, but both plantar reflexes were now flexor. Muscular power seemed good and sphincter control normal, and he was allowed out of bed. By May 12 he could walk, though with an unsteady and jerky gait, and he was discharged on May 14. Although at this time his sight was very poor, he could, by peering closely at objects, see all colours but red.

Follow-up.—After discharge he made steady general progress, and on June 2, 1949, he walked well, apart from a little clumsiness in the right leg. There was still a slight increase in all deep reflexes, and the abdominal reflexes were absent. Visual improvement was slower, but on June 24 Mr. Gibson Moore reported 6/60 vision in both eyes, though both discs remained pale. By Aug. 4 the patient could fish, swim, see better, and recognise red objects. By April 19, 1950, he could read the smallest print at two feet, but his mother thought that he occasionally mistook objects at a distance. On Jan. 1, 1951, when the patient had been back at school two terms, Mr. Gibson Moore found 6/12 vision in each eye and bilateral optic atrophy. As at the previous and subsequent examinations, the tendon-jerks were very brisk and the abdominal reflexes absent, but the plantar reflexes were flexor. At the final examination on Dec. 21, 1951, shortly after his 10th birthday, he was very well and alert. Mr. Gibson Moore now found 6/6 vision in both eyes, and though both discs were slightly pale their appearances were within normal limits.

DISCUSSION

This example of a rare complication of measles has been described in detail because it emphasises the potential recoverability of all the lesions of measles encephalitis, a toxic degeneration rather than an inflammation. Though cerebral recovery is less general than optic-nerve recovery, the ophthalmic lesion may cause the greater immediate distress, and it is essential to sustain hope in the patient and his relations during the period of blindness. This condition, however, is not often encountered. Ford (1928), reviewing the reports published in the previous sixty years, found only 111 cases of measles encephalitis, and among these only 6 cases of papillœdema; and Litvak et al. (1943) found 4 cases of papillœdema and 3 cases of disc pallor in 56 cases of measles encephalitis. In Ford’s series only 1 patient became finally “ blind and an idiot.” All the others
in Litvak’s series recovered their s
That recovery of sight is always slo
by Meurer’s (1948) cases. One of his pa
in September, 1942, and had almost recover
two years later; another took ten months to
from bilateral 3/60 to bilateral 6/9 vision. The
nerve lesions are like the other neurological findings
their tendency to disappear if the case is observed for a long time. Fortunately in the present case the converse finding of the slow emergence of mental symptoms has not been noted.

I am grateful to Mr. J. Gibson Moore for his reports on the progress of the eye condition in this case.

“MILK POISONING” AND “CALCIUM GOUT”

E. G. McQueen

M.B. Sydney, M.R.C.P., M.R.A.C.P.

CHIEF ASSISTANT TO PROFESSOR OF MEDICINE, UNIVERSITY OF QUEENSLAND; VISITING PHYSICIAN, REPATRIATION GENERAL HOSPITAL, GREENSLOPES

In the following case sudden and painful swelling of the joints resembling gout occurred repeatedly in a patient who had been drinking large quantities of milk.

CASE-RECORD

First Admission

A man, aged 56, was admitted to the psychiatric wards of a Brisbane hospital on July 10, 1950, complaining of loss of energy, insomnia, irritability, depression, weight loss of 2 st., and loss of libido. These symptoms had been present since January. He had had a duodenal ulcer since 1944 and had been on an ulcer diet, ‘Amphojel,’ and alkaline powders on and off ever since.

On admission he was dejected and tearful and had a pronounced digital tremor. His pulse-rate was 136 per minute and his blood-pressure 140/100 mm. Hg. There were two hard lumps on his left forearm, each about 5 cm. long by 3 cm. across, one over the base of the first metacarpal and the other over the head of the radius. Radiography on Aug. 12 showed deposits of opaque material on the radial side of the left wrist (fig. 1).

On further inquiry the patient said that since January, 1950, he had been drinking about a gallon of milk a day. He had continued taking amphojel and alkaline powders alternately, each for about a month at a time. He had not noticed the lumps until July when an extremely painful, tender

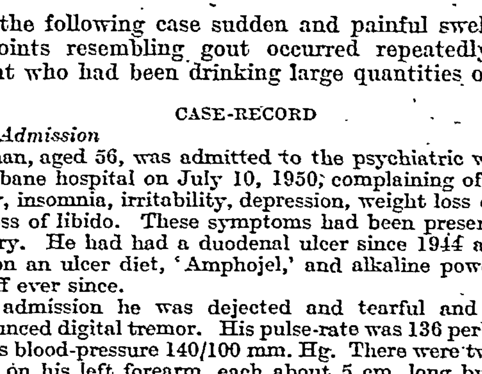

Fig. 1—Radiograph (Nov. 6, 1950) showing calcium deposits on the radial side of the left wrist.

swelling developed in the wrist and dorsum of his left hand. The swelling disappeared in about a week, but the lumps at the lower end of the radius remained. The same process was presently repeated at the elbow.

A further physical finding, evident when I first saw the patient on Sept. 8, was the presence of white chalk-like plaques in the sclera of each eye, but the fundi were normal.

Further radiography revealed gross calcification in several other areas, including the iliac arteries and the radial arteries. No calcification could be demonstrated in the renal areas, however, and the renal outlines appeared normal.

The urine was alkaline, with a specific gravity of 1·010, and consistently showed a cloud of albumin. Microscopy on several occasions showed a few leucocytes, a few epithelial cells, and an occasional hyaline cast, but no casts of other types and no red cells. Culture was repeatedly sterile. A urea-clearance test on Aug. 22 showed a maximum concentration of 1·72 g. per 100 ml. and a standard clearance of 16% of average normal.

Numerous blood studies (table I) showed a high level of serum-calcium and CO_2 combining-power (even after alkalis were withheld from the diet), a high serum-urea, and a normal serum uric acid, serum-phosphorus, and serum alkaline phosphatase. The erythrocyte-sedimentation rate was rapid.

Treatment consisted in removing all calcium-containing foods from the diet and withholding all alkalis except aluminium hydroxide. Belladonna and barbiturates were given to help control his ulcer symptoms. On this régime, his general condition improved and his mental state returned to normal. The lumps at wrist and elbow diminished in size and soon were no longer palpable (fig. 2).

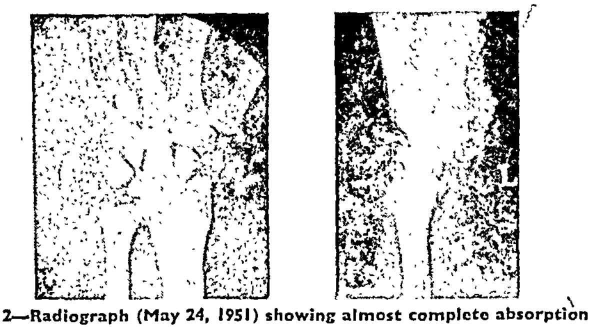

Fig. 2—Radiograph (May 24, 1951) showing almost complete absorption of the calcium deposits seen in fig. 1.

A barium meal on May 17, 1951, showed an ulcer in the first part of the duodenum and some delay in the stomach emptying-time, about half of the barium remaining in the stomach after 8 hours. After 24 hours the stomach was empty.

He was discharged from hospital in June, 1951, with instructions to follow his milk-free, alkaline-free diet. At this time his blood-pressure was 110/70 and a blood examination showed: red cells 3,200,000 per c.mm., hæmoglobin 9·4 g. per 100 ml., white cells 14,000 per c.mm. (neutrophils 83%, lymphocytes 13%, monocytes 2%, eosinophils 2%).

Second Admission

At 2.45 A.M. on July 30, 1951, he reported at the same hospital stating that $3^1/_2$ hours earlier, while in bed, he had developed severe pain in the right groin. He was obviously in intense pain with his hip held in flexion. There was an excruciatingly tender swelling over the hip-joint and the anterolateral aspect of the thigh.

Radiography on the day of admission showed enormous deposits of calcium near each hip-joint. Calcium deposits were also seen in the penis (fig. 3). He said that he had not been adhering to his diet. He had been unable to refrain from drinking milk and, in fact, he had virtually become a milk addict. (On one occasion he even seized the baby's bottle from his infant grand-daughter and drained it at a gulp.) The reason for his curious behaviour apparently was that only milk gave him real relief from his ulcer pain.

Blood biochemical findings during his second admission are shown in table II. His urine contained no albumin or other abnormal constituents at this time.

He was again given a calcium-free diet with olive oil after meals and supplementary amphojel and phenobarbitone. The pain in his hip subsided *fairly rapidly*, and the swelling of his thigh diminished over a period of several weeks. The radiographic report on Sept. 20 said: "The calcium deposit around the right hip-joint appears less and there is probably also some decrease in the mass about the left hip. The penile accumulation is unchanged, and also that in the large arteries."

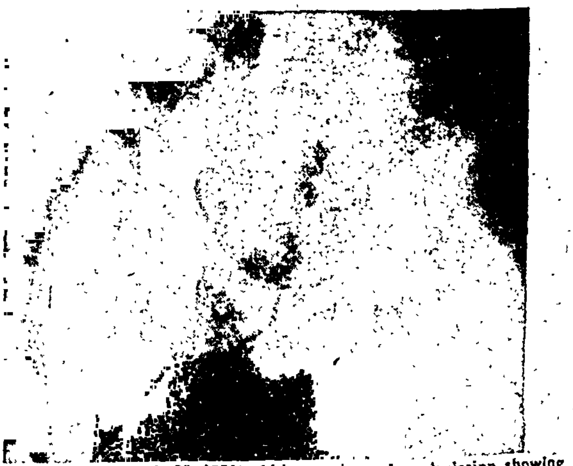

Fig. 3—Radiograph (July 30, 1951) of hips at time of readmission, showing extensive deposits of calcium about both upper femurs. Also calcium deposits in the penis.

DISCUSSION

To turn first to the metastatic calcification. The lesions in the eyes are not unique; they are recognised sequelæ of hypercalcæmia (Walsh and Howard 1947). The manner in which the deposits at the wrist, elbow, and hip (calcinosis) first showed themselves is striking in its resemblance to acute gout. The excruciatingly painful, exquisitely tender swellings, *coming on within*

a few hours, then subsiding only to recur in the vicinity of another joint, invites a comparison with gout strengthened by the similarity of the residual deposits to gouty tophi.

In fact, the sequence of events recalls those I believe to take place in gout (McQueen 1951): the capacity for holding calcium in soluble form having been exceeded, calcium began to be deposited in insoluble form. In this case, as in uric-acid gout, the deposits gave rise to signs of inflammation.

In the differential diagnosis the first condition springing to mind is hyperparathyroidism secondary to chronic renal disease. Several important points are against this diagnosis, however. Firstly the serum-phosphorus was always normal or only slightly raised. Phosphorus retention is thought to be the first step leading to secondary parathyroid hyperplasia (Albright and Reifenstein 1948): the adult cases of Gilmour (1947) and the one case of Richards (1951) all had high serum-phosphorus levels. Secondly, the serum-calcium was raised, not lowered. It is true that the patient's excessively high intake of milk might have counteracted the usual tendency in cases of hyperparathyroidism toward a low serum-calcium, thereby preventing resorption of calcium from the skeleton with consequent osteitis fibrosa. It might also explain the normal serum alkaline phosphatase, but one would have expected this to become raised during the long period in hospital when the calcium intake was negligible. Further, the high CO_2 combining-power, even after cessation of alkalis, is against a diagnosis of secondary hyperparathyroid disease.

Primary hyperparathyroidism cannot be excluded without tests of calcium excretion. However, the absence of skeletal changes, and the normal serum alkaline phosphatase after restriction of calcium intake, make this diagnosis unlikely.

Burnett et al. (1949) have described a syndrome characterised by:

> ". . . a history of prolonged and excessive intake of milk and absorbable alkali; hypercalcæmia without hypercalcuria or hypophosphatæmia; normal serum alkaline phosphatase level; marked renal insufficiency with azotæmia; mild alkalosis; calcinosis manifested especially by an ocular lesion resembling band keratitis; and an improvement in the clinical state on an intake low in milk and absorbable alkali."

The development of this syndrome may not be possible in the absence of renal disease. The only case in Burnett's series which came to necropsy had pyelonephritis (and nephrocalcinosis), although in one of his cases renal biopsy was normal two years before the development of renal insufficiency. My own patient had undergone repeated routine examinations before the onset of his present illness (he had been in hospital for treatment of his ulcer in 1944, 1947, and 1948), and no record had ever been made of a urinary abnormality.

Long-continued and excessive consumption of alkalis may be prerequisite for the development of this syndrome and may possibly be responsible for initiating the renal damage. Burnett et al. (1950) have shown damaged renal function 17 months after acute episodes of alkalosis. Actually there had been no acute episode of alkalosis in the present case; the patient had been taking alkalis for years and there had been no bout of vomiting or other disturbance likely to precipitate alkalosis.

The onset of his present symptoms dated from the time he started drinking an enormous amount of milk. But when milk and other calcium-containing foods were removed from his diet the symptoms and most of the calcium deposits disappeared. I think therefore that this may truly be called a case of "milk poisoning."

I would like to thank the Chairman of the Repatriation Commission for permission to publish this article.

Preliminary Communication

RELATION BETWEEN IN-VITRO AND IN-VIVO RESISTANCE TO ISONIAZID

It is now established that tubercle bacilli can develop resistance to isoniazid and related compounds both in laboratory media and in patients undergoing treatment with the drugs.[1] The relation between in-vitro and in-vivo resistance, however, is not clear and there are conflicting reports as to the rapidity with which they may develop. The experiments here described show (1) that resistance can be rapidly developed in vitro by subculture at appropriate intervals, and (2) that organisms made resistant in vitro are resistant to the action of the drug in vivo.

In-vitro Production of a Resistant Strain

A culture of *Mycobacterium tuberculosis* H37RV (obtained from Dr. R. J. W. Rees of the National Institute of Medical Research) was incubated in a series of tubes of Dubos's liquid medium containing falling concentrations of isoniazid. (The concentrations referred to here are the *initial* concentrations. This is an important point, since we have found that the drug is inactivated at 37°C even in uninoculated medium. Experiments demonstrating this effect will shortly be reported.)

During the first 2 weeks of incubation, growth was inhibited at a level of 0·01 µg. per ml., but after 25 days of incubation the tube which had contained initially 1·6 µg. per ml. showed profuse growth. One drop was transferred from this tube to a fresh set containing falling concentrations of the drug. In this series growth was inhibited at first at a level of 1·6 µg. per ml., increasing during further incubation to 8 µg. Subculture was made after 19 days of incubation from the tube which had received 1·6 µg. per ml. into a similar series of tubes, and in this set growth rapidly occurred in as much as 25 µg. per ml. On subculture from this tube after only 10 days of incubation into a fresh set, good growth occurred after only 7 days' incubation in 62·5 µg. per ml. The organisms, therefore, were now about 6000 times more resistant than in the original culture.

A subculture was made from this tube into drug-free Dubos's medium and used for the animal experiments here described. The sensitivity of the actual culture used was found to lie between 8 and 40 µg. per ml.

In-vivo Results

For the screening of antituberculous drugs in vivo the experimental induction of intracorneal tuberculosis in mice has provided the basis of a satisfactory technique.[2] Conditions are standardised so that the mice, under deep ether anæsthesia, are each inoculated intracorneally in one eye with about 1000 viable organisms of *M. tuberculosis.* Thereafter, in the absence of treatment, a characteristic tuberculous lesion appears after an interval of about 11–14 days. Over the ensuing 2 weeks it proceeds to involve the greater part of the cornea, remains stationary for some time and subsequently undergoes some spontaneous regression.

When such mice are treated with an effective antituberculous agent, however, the course of the disease may be modified in various ways. There may be suppression altogether; there may be inhibition while treatment is maintained but recrudescence later with undiminished vigour; there may be some

alteration in the advance of the disease, both in extent and time.

Using this method, the efficacy of isoniazid in the control of experimental tuberculosis has been satisfactorily demonstrated.

In one group of male albino mice, infected intracorneally with a virulent human strain of *M. tuberculosis* (H37RV), the disease followed its expected course and the great majority of animals were eventually involved. Treatment with isoniazid completely prevented the development of any ocular lesions during the period of administration of the drug, a result very similar to that already reported with thiosemicarbazones.[3]

When the same experiment was repeated with the in-vitro resistant strain (described above) the result was entirely different. In all such experiments with isoniazid the mice received 0·3 mg. per mouse per day in the food (equivalent to about 12 mg. per kg. body-weight). The treated animals developed lesions of exactly the same kind as the untreated control mice; in both groups (each containing 10 mice) there was the usual latent period of some 14 days and then the lesions developed rapidly.

There is now a clear indication that resistance to isoniazid does develop in patients treated with the drug, and such results are in fact being obtained in clinical investigations at present in progress at Guy's Hospital. The evidence for this conclusion is, of course, based on measurement of resistance performed in vitro on organisms recovered from such treated patients. The results here described show that such in-vitro data are in fact relevant to conditions in the living body and that such resistant organisms can produce pathological changes in the course of treatment with isoniazid.

We are greatly indebted to Mr. D. E. Seymour of Herts Pharmaceuticals Ltd. for the supply of isoniazid used in these experiments.

Reviews of Books

Film in Education

ANDREW BUCHANAN, D.LITT., PH.D., F.R.S.A. London: Phœnix House. 1951. Pp. 256. 25*s.*

FILMS are already playing a large part in modern education and cover a number of subjects ranging from science to the fine arts and religious instruction. The possibilities of extension are limited mainly by the cost of production. In medicine, films can never take the place of practical contact with patients, but thanks to their ability to compress time they can usefully illustrate the progress of disease over long periods. They can also be used to demonstrate procedures such as surgical operations, and prolonged physiological studies such as the determination of the cardiac output; and diagrammatic films can clarify such things as complicated biochemical reactions or integrate multiple ætiological factors into a unified scheme of causation.

Dr. Buchanan's book covers almost every aspect of educational film work from production to the details of projection, and it is thoroughly informative. Although he writes as an enthusiast holding clear-cut opinions, he is careful to demand for films no more than their just place as an instrument of a general educational purpose, and does not offer them as a substitute for other methods of teaching. The place of teachers in the use and in the making of film is also set out in this useful and readable book.

Manual of Leprosy. *Supplement to the 1st. edition.*

ERNEST MUIR, C.M.G., C.I.E., M.D., F.R.C.S.E., medical adviser, British Empire Leprosy Relief Association. Edinburgh: E. & S. Livingstone. 1952. Pp. 16. 2*s.* 6*d.*

THIS supplement to the "manual" published in 1948 is particularly welcome, for it brings a rapidly developing subject up to date. Where leprosy is concerned there is a tendency to err on the optimistic side; and emphasis on the cheapness of treatment and the efficacy of present-day drugs may lull the profession into complacency. The discovery of an effective remedy for leprosy does not mean we are yet within reach of its final control. The scheme of dosage of the sulphone preparations recommended by Dr. Muir is in accordance with the regimen now accepted, and he insists that physicians must start with low doses and gradually increase them. Those who follow his detailed instructions should not go astray. For routine use he advises oral diamino-diphenyl-sulphone, but emphasises that this should only be the method of choice for those "who are sufficiently educated and responsible to be trusted to take tablets regularly." He might have given more attention to the toxic signs, particularly with D.D.S., for these are often a cause of concern. Desensitisation is mentioned when a toxic dermatitis supervenes, but not the dosages of aqueous 'Sulphetrone.' Those recommended by Lowe and Davey (*Trans. R. Soc. trop. Med. Hyg.* 1951, 44, 634) are very small—20–200 mg. twice weekly over 4–5 weeks. More space might have been given to reaction in leprosy, and it would have been useful to differentiate between the erythema-nodosum phenomenon, which is passing and generally speaking favourable, and the more serious progressive lepra reaction, which may be much more formidable, and carry a more serious prognosis. It may also be confusing for the general physician, for whom the manual was written, to introduce such drugs as streptomycin, of which the expense and inconvenience have proved to be out of proportion to the results. Thiosemicarbazone is rightly mentioned, but no indication is given of its dosage. The impression left on the reader's mind is that the only sulphone worthy of attention is the parent sulphone, diamino-diphenyl-sulphone; but there are preparations which are almost as cheap and which some workers regard as less toxic yet equally effective.

Ruptures of the Rotator Cuff

H. F. MOSELEY, M.CH. Oxfd, F.R.C.S., F.A.C.S., assistant professor of surgery, McGill University. Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 90. 47*s.* 6*d.*

Dr. Moseley's little book is in the American Lectures in Surgery series and as such presents didactically, with a minimum of discussion, his views on the diagnosis and treatment of the rotator tendon injuries at the shoulder. Starting from Codman's emphasis on the supraspinatus, he proceeds to include lesions of the subscapularis tendon; normal and pathological anatomy and operative repair are illustrated by diagrams of great clarity and beauty, though the few photographs of actual specimens are less satisfactory. He relies considerably on the procaine test, advising operation when this restores active abduction but the power of abduction against resistance remains greatly diminished. In this country opinion would usually be against operation unless abduction remained impossible after procaine infiltration. His emphasis on the necessity for operation if a good functional result is to be obtained is not in entire accord with the good results which may be obtained with conservative treatment, or with the finding—by De Palma and others—that perfect function during life may be compatible with massive cuff injuries found at routine necropsy. Good simple methods of measuring shoulder-joint and shoulder-girdle range and power are shown. It is interesting to note that although the Canadian winter prevents the routine use of abduction splints after operation, patients seem to do just as well if the arm is kept—as Codman originally advised—in a sling by the side.

THE LANCET

LONDON: SATURDAY, JULY 12, 1952

Sore Throat and Rheumatic Fever

Acute rheumatic fever is a complication of a group-A β-hæmolytic streptococcal infection of the throat of a susceptible person. This is a proposition which is now well established, and its corollaries seem equally sound—namely, that infection by no other organism gives rise to acute rheumatic fever, and that all patients with acute rheumatic fever have had antecedent streptococcal throat infections. Medical science has a way of finding exceptions to such dogmatic statements, but the general truth of these is widely accepted. It follows that if one can prevent streptococcal throat infections one can prevent rheumatic fever, and this too has been abundantly confirmed. What we do not know is why, of 100 patients with apparently identical infections of this type, 98 recover completely and 2 get rheumatic fever.

To Coburn[1] in the United States, and to Schlesinger[2] and Sheldon[3] in this country, goes the credit for bringing again to general notice the clinical relation of upper respiratory infection to rheumatic fever, the evidence for which was reviewed many years earlier, in 1899, by Pribram.[4] Serological analysis of streptococci by the method of Lancefield[5] has shown that only upper respiratory infections caused by the group-A β-hæmolytic streptococcus are involved, and other evidence for this relationship has been provided by epidemiological studies following the pioneer work of Glover[6] in this field.[7, 8] Yet further evidence is given by a study of the antibodies found in the blood; recently Swift[9] could show that, of a group of patients with rheumatic fever, all showed antibodies to one or other of the antigens of the group-A β-hæmolytic streptococcus in titres suggesting recent infection. But while it has been possible to prove that there is a relation between throat infection and rheumatic fever, we are still uncertain about its nature. The opinion most widely held is that rheumatic fever is a disordered antibody-antigen reaction following the repeated absorption into the body of some product of the streptococcus, analogous to the serum-sickness following injection of foreign serum. The immunology of the group-A β-hæmolytic streptococcus has been extensively studied, but none of the many antigens produced by this organism has yet been incriminated.

However, the man who knows nothing about the chemistry of combustion is none the less able to avoid putting his fingers in the fire, and attempts at preventing rheumatic complications by avoiding or preventing the initiating streptococcal infection have met with striking success. In the past it has been supposed that removal of the tonsils would decrease the incidence of rheumatic fever, but this is not borne out by experience.[10] The recent war, by ensuring that young men were herded together in barracks, camps, and ships, afforded many opportunities for the epidemic spread of streptococcal infections, which left rheumatism in their wake. Pioneer work by Thomas and France,[11] and by Coburn and Moore,[12] in 1939 led to the use of sulphonamides in small doses to prevent this spread of infection, and the incidence of both streptococcal infection and rheumatic fever was reduced. Once a throat infection is established, however, sulphonamide treatment is of no use in preventing rheumatism; and, while it has proved safe enough to use sulphonamide to protect a particular person from streptococcal infection at home or in hospital, long-continued use of this agent in the mass prophylaxis of all members of a closed community has so altered the bacterial environment that, when sulphonamide-resistant strains of group-A β-hæmolytic streptococci emerged, their pathogenicity and spread was actually enhanced—a counter-attack by the organism only controllable because penicillin was now in reserve.[13]

Much of the early work with sulphonamides was repeated with penicillin when this antibiotic grew plentiful; and it became apparent not only that penicillin was equally effective in preventing streptococcal infections[14, 15] but also that early vigorous treatment of exudative tonsillitis could abort these infections quickly enough to reduce the likelihood of subsequent rheumatism. The largest studies on this subject have been those of Rammelkamp and his associates[16] at a large American Air Force training base. In their investigation 1178 randomly selected patients with exudative tonsillitis received penicillin and 1162 patients with the same diagnosis served as controls. In the thirty-four days following the onset of the sore throat 23 of the control patients developed rheumatic fever (an incidence of approximately 2%), but only 1 of the treated group showed this complication—and here there was evidence of an intercurrent untreated reinfection. Rammelkamp[17] emphasises that penicillin treatment should be early and that the case of sore throat caused by the group-A β-hæmolytic streptococcus is usually characteristic enough to make bacteriological confirmation unnecessary before starting treatment. Typically there is a relatively rapid onset with soreness in the throat on swallowing, painful and swollen cervical lymph-nodes, malaise, and fever. Young patients often vomit during this period. On examining the throat one sees general swelling of the lymphoid tissues of the pharynx and a bright-red inflammation of faucial mucosa. On the tonsils, discrete or confluent patches of yellow exudate

stand out clearly against the red background. The concept of a clinically recognisable group-A β-hæmolytic streptococcal sore throat is supported by the experience of Rantz et al.,[18] but recent careful studies in this country [19, 20] show that there may be considerable overlap between the symptoms and signs of sore throats which yield a positive throat culture for this organism and sore throats which yield commensals. Nevertheless, all observers agree that most of the more severe sore throats are caused by this group of streptococci, and it therefore seems reasonable policy to treat all moderate or severe sore throats with penicillin by intramuscular injection (Rammelkamp [17] recommends at least two injections of 600,000 units of procaine penicillin G in oil with 2% aluminium monostearate at a three-day interval). Mild sore throat, on the other hand, need not be treated unless there is known to be an epidemic of group-A β-hæmolytic streptococcal infection or unless there is evidence of a personal or family predisposition to rheumatic fever. Widespread application of this policy should lower the incidence of rheumatic fever and of rheumatic heart-disease. Indeed the more effective treatment of sore throat may be partly responsible for the decline in the incidence of these conditions in recent years, although this decline began before the era of antibiotics.

What of the patient who has already had one attack of rheumatic fever? Here the situation is somewhat different, for it is estimated that about half of these susceptible people who have further attacks of streptococcal infection suffer recrudescence of rheumatism.[21] Moreover, the infection which provokes the recrudescence may be mild and little more than the symptomless carrier state. Because of this special risk, Rammelkamp thinks it unjustifiable to await symptoms of infection before attacking the organism; treatment should be continuously given to *prevent* infection. It is in this group of patients that a small daily dose of an antibiotic can substantially decrease the recurrence-rate of rheumatic fever; though in some 10% of patients the infection "breaks through" the protecting antibiotic. From the standpoint of protection from rheumatic recurrence there seems to be little to choose between a small daily dose of a sulphonamide (such as 1·0 gramme of sulphadiazine) and a daily oral tablet containing perhaps 100,000 units of penicillin. The sulphonamide is the cheaper to give, but in a small proportion of cases it will give rise to signs of toxicity, which, though they would be promptly recognised and dealt with if the patients were still in hospital, may lead to serious complications in patients at home. Oral penicillin is safer and less liable to breed resistant organisms, but it is more expensive and its absorption from the alimentary tract is somewhat variable, though this can be improved by giving the tablets between meals and accompanying the dose with an antacid.[22] In the régime used by Pitt Evans [23] the rheumatic child received 100,000 units in 5% glucose solution three-quarters of an hour before breakfast.

Children recovering from rheumatic fever should, Rammelkamp suggests, be given chemoprophylaxis with one or other of these antibiotics for at least two years, and some would say even longer. Studies such as that by Bland and Ducket Jones [24] have shown that the rheumatic child runs his greatest risk of developing a recurrence (about 20%) in the first five years after an attack. Since, with the passage of time, the liability to recurrences dwindles, and after the age of puberty [25] falls sharply, a case could be made for continuing chemoprophylaxis until, say, the age of sixteen; but, as Batten [26] recently pointed out, the loss as well as the profit of prophylaxis on such a scale must be accounted for, and to subject children to daily medication throughout their most formative years may well entail avoidable cardiac neuroses. In addition, the practical implications of a general policy of chemoprophylaxis have as yet to be faced. As Dr. Gale, Dr. Gillespie, and Professor Perry point out on another page, chemoprophylaxis of outpatients, as opposed to those children still in hospital or in convalescent homes, may fall short of complete success because of the difficulty of ensuring that patients receive and take their tablets. Moreover, if prophylaxis is to become routine, more supervision will be needed of the large number of children who will require it. The current reported prevalence of rheumatic fever in this country is somewhere between 0·5 and 2 cases per 1000 of the child population, making a total of about 15,000 cases, each of whom would have to be seen regularly for two to three years. At each attendance the child would be examined for recurrence of rheumatic activity or for toxic effects of the antibiotic; and it might be thought necessary to test the urine as a check on whether the tablets were being taken. Outside those centres which already conduct frequent follow-up examinations on children who have had rheumatic fever [27] such work could not be done very readily and it would be expensive. Against this must be set the fact that rheumatic fever and its sequelæ are among the major causes of loss of years of life and of capacity to do productive work—a cost to the country which must, in comparison, be enormous.

It cannot be claimed that these methods, even if widely applied, will ever prevent all cases of rheumatic heart-disease; for about half of those who have rheumatic heart-disease have never had a manifest attack of rheumatic fever. Furthermore, daily chemoprophylaxis of group-A β-hæmolytic streptococcal sore throats is for practical reasons limited to prevention of recurrences in those who have *already* had one attack of rheumatic fever—a procedure which will decrease the mortality and morbidity of recurrences but may not decrease the cardiac damage initiated by the first attack, for the simple reason that prognosis is not closely linked with the number of attacks.[28] Despite these limitations, chemoprophylaxis is the most powerful weapon that we have in the fight against this important disease, and there is now enough evidence to justify its use much more widely than at present.

Faulty Feet

IN recent years there has been growing awareness that foot health is important, not only to the individual but also to the economy of the nation. During the late war the great prevalence of serious foot defects among young entrants to the Services came as a shock to those who examined them, and caused lively concern to the authorities: paradoxically, while Napoleon could say that an army marched on its stomach, the highly mechanised army of today depends increasingly on the state of the feet of its combatants. In industry, too, the increasing tempo of modern life brings more sharply into focus the economic wastage from the defective foot. Geriatricians, again, find that the state of the feet is one of the larger factors in determining whether old people can continue to lead useful and active lives. Foot ailments have effects out of all proportion to their intrinsic seriousness; and in an ageing population this is a factor of increasing importance. It has been rightly said that foot ailments are one of the major evils of modern society; yet little has been done on a national scale in the way of preventive care, compared with that bestowed, for example, on the teeth and the eyes. Before embarking on large measures, however, we need to know the nature and the extent of the problem. Although a number of surveys have dealt with specific aspects, none has hitherto been undertaken with the object of giving a general picture of the prevalence of the various types of foot ailment in the general population at all ages. To fill this gap, Dr. DYKES and his colleagues [1] made a survey in Luton, and their findings provide illuminating answers to a number of cogent questions. The survey was conducted by means of a questionary which was sent to a random sample of the population, and the replies were checked by personal examination of a sub-sample. The resulting figures lead DYKES et al. to the somewhat alarming conclusion that about 30% of the population have a foot defect of one kind or another. A visible defect does not, however, necessarily entail pain or disability; and it is unfortunate that in this survey defects causing symptoms are not more clearly distinguished from those unassociated with symptoms. For years orthopædic surgeons have held that in the adult the commonest cause of foot disability is not "flat-foot" but defects of the forefoot and toes, and that these conditions originate in childhood. This survey, like others before it, shows that whereas in the 0–14 year age-group the "flat-foot" and "valgus ankle" complex outnumbers forefoot defects by 7 : 1, from the age of 25 years onwards the ratio is reversed at 1 : 5. Moreover, after the age of 14 years the incidence of symptoms from forefoot defects increases rapidly. Since in children mechanical defects have to be quite severe before giving rise to symptoms, the defects themselves must arise at a much earlier age. Thus the most significant facts confirmed by this survey are the great prevalence of foot disabilities in the population, the major rôle of defects of the forefoot and toes, and the early age at which such defects originate.

Clearly the problem can be effectively tackled only by preventive measures in childhood. This implies, first, the organisation of suitable schemes for the inspection of children's feet at various ages, and, secondly, suitable provision for the care and supervision of those noticed to have defective feet. A useful lead is given in a pamphlet just published by the Foot Health Educational Bureau,[2] which puts forward definite proposals for preventive measures that could be undertaken within the present economy of local health authorities. We hope that medical officers of health will study these suggestions and try to adopt those suitable to their own particular circumstances; for it is only by local experiment and experience that a national policy can be evolved.

New Ideas for Cancer Research

AN appeal is often heard for more synthesis and less collection of facts in cancer research; but provided that the facts are new and not mere elaborations and repetitions, they should be welcomed, for all are needed to solve the many problems of this intricate disease. In the 29th annual report of the British Empire Cancer Campaign [3] many new data are added and two welcome attempts are made to blend older information.

Differences between species in susceptibility to induced cancer compel caution in deducing that what is true for one may apply to others; and hitherto these differences have not been explained. The difference in response of man, dog, and the smaller laboratory animals to ingestion of chemicals which in some cause bladder cancer is one that has greatly hampered experimental work aimed at the detection of the substance or substances responsible for industrial bladder cancer in man. The explanation of this particular species difference lies almost certainly in differences in metabolism. It has long been known that β-naphthylamine (now called 2-naphthylamine), an intermediate product in the dye industry, will induce bladder tumours in man by absorption through lungs, mouth, and skin. In dogs oral administration induces such tumours, but in other laboratory animals this chemical seldom has such an effect. The discovery, reported last year by G. M. BONSER and her colleagues,[4] that the compound which is actually effective in the bladder is more likely to be 2-amino-1-naphthol, a metabolite, than the parent amine has now been confirmed and extended. This view rests on the evidence that when in mice 2-amino-1-naphthol was introduced directly into the urinary bladder in pellets, some bladder carcinomas arose locally, even though mice are insusceptible to the parent amine by ingestion. Furthermore, conjugates of 2-amino-1-naphthol are excreted in the urine of the dog in amounts approximately equivalent to the dose of parent amine, whereas under equivalent conditions of dosage they fall from species to species in the order cat, ferret, rat, mouse, rabbit. Again, the conjugates excreted in the urine of the dog are highly concentrated compared with plasma; and traces are found in the urine of dye workers. Last week at a meeting in Glasgow of the Pathological Society of Great Britain and Ireland, the additional information was given that the parent amine itself was ineffective in pellets introduced into the mouse bladder. Here, then, we have a most useful new technique which does not require unusual skill,[5] a synthesis of knowledge which has been patiently garnered over many years, and the first reported explanation of variation in species susceptibility.

While the story of bladder cancer is well on the way to full substantiation, the second attempted synthesis is still somewhat more speculative. Attention was first drawn by F. D. ASPLIN and E. BOYLAND[6] to the capacity of sulphadimidine to induce hypertrophy and hyperplasia of the testis, with precocious comb growth, in young cockerels. This odd result was independent of bacteriostatic properties or mediation via the anterior lobe of the pituitary. These workers found, in collaboration with W. C. J. Ross, that another pyrimidine derivative, xanthopterin, produced hypertrophy of the kidney of rat and mouse due to a great outburst of mitosis of tubular epithelium. The view was taken that the stimulus to mitosis was direct, and not due to destruction and regeneration with hyperplasia. This is very likely correct because xanthopterin is a natural product in the body. If so it takes its place among the few known direct stimuli of cell division. The hormones and their target organs are other examples. This new observation has led to intensive studies because of the intrinsic importance of xanthopterin in regulating normal cell division and the part that it may play in the continuous multiplication of tumour cells—presumably kidney tumour cells. It is at this point that speculative synthesis is being attempted. Two main hypotheses are being examined by Prof. A. HADDOW and a team at the Royal Cancer Hospital. The first supposes that while xanthopterin is a specific stimulus to division of cells of the renal tubules, other substances, including certain imines, have the same effect by inhibiting xanthine oxidase, and thus allowing the accumulation of xanthopterin as one of its substrates. The second view supposes that xanthopterin itself inhibits xanthine oxidase. If, now, there occurs in a cell a loss of this enzyme system governing xanthopterin production and output, xanthopterin might provide that continuous stimulus to division which is the basic property of tumour cells. Here the unproved assumptions include the loss of the enzyme system and continuous production by renal tumours of xanthopterin. This might readily be settled by the use of Lucke's adenocarcinoma of the leopard frog. It might be found that the virus causing this tumour effects deletion of the enzyme system. Continuous production of xanthopterin after infection of the renal cells might then be sought.

FACT AND THEORY IN INFLUENZA RESEARCH

IN a most interesting series of talks on the Nature of Scientific Theory, broadcast recently in the Third Programme, Mr. S. E. Toulmin discussed the differences between logicians and scientists in their attitude to scientific theory. Logicians, according to Mr. Toulmin, expect the scientist to do each experiment five hundred to a thousand times; the greater the number of experiments, the more certain the scientist can be of his results and conclusions. This view has arisen, however, from a mistaken idea that scientists are all naturalists who simply observe and record their results. In fact, Mr. Toulmin pointed out, the outlook of the natural historian has little influence on present-day scientific theory, which is more in the nature of a map, showing a range of phenomena as an ordinary map shows a stretch of country. It is seldom necessary for a scientist to repeat an experiment more than three or four times before he can legitimately begin to construct his hypotheses. The speaker was being generous in his estimate; many scientists construct their theories after two, one, or no experiments.

If we may distort Mr. Toulmin's analogy a little, the place-dots on a map may be likened to experimental facts and the contour lines to theories relating these facts. The centre of the map is printed in bold type and describes the body of accepted knowledge, while at the periphery the dots and lines are fainter. We may liken a scientific paper to an attempt to fill in a few more dots and lines at the edge of the map. Some scientists take great pains with their dots, surrounding each with a small circle to indicate their experimental error, and sketch in only a few modest dotted lines, almost as an afterthought. Other scientists draw bold lines which join up a few modest, perhaps even nebulous, dots.

Examples of the different methodologies can be found in the June issue of the *Journal of Hygiene*, which contains two papers describing the results of research on the influenza viruses. Fulton's paper[1] is a careful account of a method for titrating influenza virus neutralising antibodies, using a new technique[2] for cultivating the virus in fragments of chick chorio-allantoic membrane. The precision of the test is matched by its elegance. An interesting outcome of this work is the slight serological relation noted between the WS strain of influenza A and strains of influenza B virus. This result may be another serological coincidence similar to the relation between antigens of proteus and the rickettsiæ, or it may be a faint hint of a common parentage. Hoyle's article[3] is an imaginative account of the structure of the influenza virus in relation to its method of multiplying. The theory follows the author's earlier lines of thought; the virus is conceived of as entering a susceptible cell and breaking up into smaller units of self-replicating soluble antigen which later recombine with specific antigen derived from the original inoculum. This hypothesis demands that the soluble antigen should contain nucleoprotein, since self-replicating units have nearly all been shown to contain nucleoprotein. Hoyle describes experiments which lead him to conclude that the soluble antigen is a ribonucleoprotein. In the absence of chemical estimations, however, the tests with enzyme preparations have to be interpreted cautiously; thus many-times crystallised preparations of ribonuclease have been shown to contain small amounts of protease which might upset the best-laid plans. Hoyle's ideas on influenza virus multiplication are arousing much interest; but they are a long way ahead of the known facts.

One well-known scientist used to suggest that all scientific journals should be printed in two colours—black for fact and pink for imagination—and he added that very little black ink would be needed. Nevertheless, in any scientific work, fact and theory are strongly interdependent, and the one without the other is like meat without drink. It is for the scientist to find the proportion of theory that will stimulate without intoxicating.

AS A PATIENT SAW IT

WHEN patients speak their minds of the nursing they receive in hospital they generally complain of lack of sympathy. That this is a judgment made partly at an emotional level is suggested by the criticisms offered by Mrs. Freda Naish at last week's conference at the Royal College of Nursing. She went into a paying ward of a large London hospital for an operation—a paying ward, as she explained, because otherwise she would have had to wait a long time for a bed, and she feared that in the interval she would develop the unpleasant symptoms so mysteriously absent in her case. No advocate of home nursing, she prefers the ministrations of professionals; but she dreaded the thought of hospital, and especially the thought of a ward full of people. She came to reverse this opinion completely, finding that she welcomed the help of the other patients. When her voice became a whisper a neighbour called a nurse for her, and in the self-pity of the days after the operation it was a good thing to see that there were others who were worse.

Unlike many another patient she did not particularly want a nurse to herself; for, as she said "how distressing it would be to find yourself allotted to the one nurse you didn't fancy." She liked the large numbers of ever-changing nurses, and when they discussed the latest hospital dance over her dressing she was reassured to feel that hers was not an interesting case. She was also unusual in liking a good deal of traffic and activity in the ward, finding it comforting, especially at night; and she even enjoyed the early start of the day. "To me the twenty-four hours seemed much the same in hospital, and it was no special hardship to go to sleep, and wake up, relatively earlier than at home."

What did try her was the ill-informed medical gossip of the other patients, and the behaviour of the ward nuisance. This lady was not nearly ill enough; she was far too mobile. Mrs. Naish awoke from sleep soon after her operation to find the nuisance holding her hand and saying: "I know just how you feel, dear. I *started* with your operation fifteen years ago." In fact the patient needs the nurse's protection, not only from other patients of this kind, but also from enthusiastic visitors. Hospital visiting hours were generous—every afternoon and evening—and relatives were allowed to see visitors in non-visiting hours. We all know that our nearest are not necessarily our dearest, and as Mrs. Naish pointed out, relations have more power to upset us than anyone else. Even visitors who are less emotionally loaded can be very tiring. She felt she was allowed far too many: "the effort of entertaining them left me quite exhausted." If she had mentioned this to the sister she would have been spared the undue strain; but with considerable insight she notes that a change came over her character in hospital: she childishly accepted everything as it came without question, and even had a childish tantrum when she was told she was well enough to wash herself.

However, as she gradually recovered her adult outlook and status she began to resent the scanty information she was given about what was after all her own body. Though the operation had been gynæcological, she had been left with a brachial palsy in her right hand, which troubled her, since dexterity is necessary to her in her profession. It was not reassuring to be told: "Yours is not nearly so bad as Mrs. X's. *She* can't even hold a cup." It is hard, however, to see what other comfort a loyal sister could offer; she was not responsible for the palsy, and could hardly criticise those who were. Mrs. Naish would also have liked more advice about how to manage her life when she left hospital, and more warning of how she would feel and what things would tire her. Oddly enough, the hospital staff would probably have been at a loss here: the proper person to help her was her family doctor. Yet the doctor received no notification from the hospital of her return home until several days later, and she herself did not know whether to report her return to her doctor or not. Something better in the way of liaison is badly needed here.

Her most important criticism, from a medical point of view, had to do with sterile technique: a young nurse, unfamiliar with a treatment, used on her a piece of apparatus which was not sterile; and she wondered, as we have often done, whether bacteriology is being taught to nurses in a way that allows them to use their imagination and fit their knowledge to circumstances as they arise. She mentioned the experience of a friend in another hospital that aseptic technique was something the nurse didn't bother about if sister wasn't looking. Such an irresponsible attitude can only be the outcome of thinking in terms of rules rather than germs. Nevertheless, one piece of laxity had her whole-hearted support. Each day, as her drainage tube was shortened, the safety-pin which prevented it from slipping into the wound had to be inserted afresh through the rubber. Under the sister's eye the nurse achieved this almost impossible feat with forceps; which meant ten agonising minutes for the patient. In the sister's absence it was done in a moment with the fingers. Surely, she says, something easier could be found? The answer, of course, is a clip properly designed to be manipulated with forceps: our surgeons and manufacturers must surely have invented one. Why is it not in use?

CARDIAC ARREST

DEATH on the operating-table is by no means rare, even in this country where the general standard of anæsthesia is as high as anywhere in the world. It has long been realised that prompt restoration of the circulation by cardiac massage may offer a chance of recovery; but reluctance to publish details of these tragedies, and the difficulty of carrying out the prompt and courageous measures that are necessary, have militated against the accumulation of much precise knowledge about the best measures in these circumstances.

Within the last few years, however, great interest has been taken in the treatment of cardiac arrest, particularly in the United States, where the standards of anæsthesia are perhaps a little more patchy than in this country; and a certain amount of exact knowledge has been gained. Experimentally Kay[1] made a study in dogs in which either ventricular standstill was produced by deep anæsthesia with chloroform or ether, or ventricular fibrillation was evoked by passing a 30-volt 60-cycle alternating current directly through the heart. In both instances cardiac massage was the most important procedure for restoring normal activity, although with ventricular fibrillation preliminary electric defibrillation proved the most successful measure, the resulting ventricular standstill being remedied fairly easily by massage and drugs. Of these drugs isopropyl adrenaline and barium chloride were the two valuable ones. Procaine proved unsatisfactory in fibrillation.

Dale,[2] reporting 12 cases of cardiac arrest, underlines once again the need for speed in treatment (although Carter[3] has lately described a case in which cardiac massage was continued for 15 minutes before the first heart-beat was felt, and was continued for altogether 25 minutes, and yet the patient recovered completely). Certain important practical clinical points are brought out by Dale. He advises that cardiac massage be proceeded with immediately the patient is pulseless and no heart-beats are heard on auscultation. An incision through the chest wall is always preferable to one through the abdomen and the diaphragm. Massage through the diaphragm he regards as inefficient and a waste of time. Dale advises incision at the 4th left interspace; the ribs spread easily if the costal cartilages

are cut above and below the interspace. No bone instruments are needed. Dale remarks that "a poorly done incision with immediate massage is better than a skilful approach if brain damage has occurred." Once the heart has responded, the operation is better deferred, or at any rate carried on only so far as is necessary to safeguard the patient's life. On the question of using adrenaline Dale points out that this, by itself, rarely restores cardiac action, and he suggests that it should be reserved until massage has been started. In the 300 reported cases found by him the mortality was 69%.

While the frequency of cardiac arrest through physiological neglect or mishandling during anæsthesia is likely to decrease with improving standards of anæsthesia, the extension of surgery, particularly of the thorax, will probably produce a continuing number of such cases. Courageous measures then lose nothing and may save a life.

NUTRITIONAL DEFICIENCIES IN NIGERIA

THE basic agriculture varies widely in different parts of Nigeria. In the north the staple food is usually guinea-corn (*Sorghum vulgare*), but in some districts large amounts of the bulrush millet (*Penisetum typhoideum*) and sweet potato are cultivated; in the south, yams and cassava are the principal food-crops. A little maize is grown, and in the small towns some white bread and milled rice are to be had. In some districts there is a plentiful supply of red palm oil, rich in carotene, whereas in others there is no oil or fat containing vitamins. Usually beef, pork, mutton, and dairy products are scarce. In a few areas fish provides a liberal quantity of animal protein. But commonly the only source of this nutrient is dried monkey, rat meat, snake meat, snails, frogs' legs, porcupine, and African weevils; and even these unusual delicacies are only to be had in very limited amounts. A wide variety of native beers and spirits are consumed. Thus the diet varies greatly from district to district. The over-all calorie content is usually adequate, but there are areas with apparent deficiencies in vitamin A, aneurine, riboflavine, nicotinic acid, calcium, and animal protein. Nicol[1] has recorded the results of six separate diet surveys in different parts of the country. In each survey the composition of the diet was determined by weighing for a week all the food consumed by the adults in the families; and in each some 80 persons were investigated.

The special interest of these surveys lies in the associations between deficiency of the various nutrients and prevalence of the various clinical stigmata of deficiency diseases. Thus in areas devoid of the red palm oil, the mean vitamin-A activity of the diets was below 750 international units (I.U.) daily. Here there was a high prevalence of corneal opacity associated with dryness of the conjunctiva, staring hair, and hypochromotrichia, general xerosis and follicular hyperkeratosis, "elephant skin," "crackled" skin, and night blindness. In the red palm oil district the average vitamin-A activity of the diets was over 5000 I.U. daily, and here the prevalence of these conditions was low. Nicol concludes that vitamin-A deficiency is an important factor in the production of these conditions. In the north one group with a high intake of sorghum consumed appreciably more riboflavine than the remainder. In this group there was less nasolabial seborrhœa, permanent gooseflesh, injection of the conjunctiva, and angular stomatitis. This suggests that riboflavine deficiency partly accounts for these signs. In two groups in the south, where little or no cereal was eaten, levels of aneurine and nicotinic acid were low and there was a high prevalence of calf tenderness (aneurine deficiency) and magenta and lilac tongues and, in one group, enlargement of the filiform papillæ of the tongue. These two changes in the tongue are attributed to nicotinic-acid deficiency. In all the peasants there was a high prevalence of folliculosis, atrophic skin, ulcers and scars of ulcers, thickened conjunctiva, and photophobia. These are probably not due directly to dietary causes, but deficiencies of the B complex of vitamins may act by exaggerating the effects of minor trauma.

Heights and weights at different age-levels were determined in four groups. In two of these with a good supply of fish, growth was appreciably faster than in the other two; and in one of these groups the final levels of height and weight were well above the remainder. This is suggestive evidence of a growth-promoting "animal protein factor."

These findings are important to the health and agricultural authorities in Nigeria. Shaw and Colville[2] have lately reported on the livestock situation in this colony. Animal husbandry is still very backward, and there is much undeveloped, potentially good stock land. They point the way to greatly increased local supplies of both beef and dairy products, which would undoubtedly raise the levels of health of Nigerian peasants. These problems must be tackled urgently if Nigerians are to take their full share in the development of Africa.

DEATH DURING ANTABUS TESTS

AN account by Becker and Sugarman[3] brings up to three the number of reported deaths due to an 'Antabus'-alcohol test reaction. Considering the widespread use of antabus, the mortality has apparently been very low. Nevertheless this new report must be taken as a serious warning to all who are using the drug. The patient was examined most carefully before being subjected to the test; the examination included routine electrocardiography, exercise-tolerance test, kidney and liver function tests, and blood chemistry studies. The clinical report gave no inkling that a severe reaction was to be expected. The patient, after receiving antabus for four days, was given 1 oz. of whisky. His reaction was very severe, and he was resuscitated with oxygen, adrenaline, and intravenous glucose-saline. Two hours later his condition seemed satisfactory; but two and a half hours after this he suddenly collapsed and died. Necropsy gave no clue to the cause of death. This case corresponds closely to that reported by Jones.[4]

Becker and Sugarman state that the dose of antabus was "that usually recommended" and that the test dose of alcohol was "well within the limits recommended in the literature." These doses were, however, larger than those recently advised by Moore and Drury,[5] who recommended a "loading dose" of 3 g. of antabus, and emphasised that a glass of beer should be used for the initial test, and spirits given only if beer produced an unimpressive reaction. Becker and Sugarman state that "it is necessary to obtain a strong test-reaction in order to teach the alcoholic patient aversion." Moore and Drury found that a "safe reaction" was quite strong enough for this purpose; and that vomiting, dyspnœa, and a fall in blood-pressure were to be avoided. Becker and Sugarman conclude: "This is not a drug to be used in general practice and dispensed in maintenance doses like digitalis. At most it may be another tool, still unproved, for the psychiatrist or those willing to devote time to the cause of the patient with chronic alcoholism."

THE 13th British Congress of Obstetrics and Gynæcology has been held this week in Leeds. On Wednesday the University of Leeds was to confer the honorary degree of doctor of laws on Dr. Albert Aldridge (New York), Prof. M. A. van Bouwdijk Bastiaanse (Amsterdam), and Sir Eardley Holland.

BRITISH MEDICAL ASSOCIATION

FOR the fourth time in its history the British Medical Association chose Dublin for its annual meeting, but this year was the first in which the meeting had been held ointly with the Irish Medical Association. The annual representative meeting was held from July 3 to 7, followed by the scientific sessions from July 8 to 11. The meeting ncluded three plenary scientific sessions—a popular nnovation—and a scientific exhibition was arranged in University College.

It was announced that H.M. the Queen has consented to become Patron of the association.

The president of the B.M.A. for 1952–53 is Dr. P. T. J. O'FARRELL, senior physician to St. Vincent's Hospital, Dublin, and consulting cardiologist to St. Kevin's Hospital, who was president of the I.M.A. for 1950–51. In his address to this 120th annual meeting he recalled that at the Dublin meeting of 1867, when scientific sessions were first held, Joseph Lister spoke momentously on the Antiseptic Principles of the Practice of Surgery. Discussing the impact of a National Health Service on both doctor and patient, Dr. O'Farrell said:

> "Although much has been written about the plight of the general practitioner, too little has been said about the reactions of the patient under the influence of State-organised medicine. Of recent years broad changes have taken place in the attitude of patients towards their illnesses. They now often welcome, and indeed demand, full-scale methods of investigation and do not mind running the gauntlet of men and gadgets. While, up to a point, this outlook is desirable, it can be abused when patients avail themselves of a service which gives them the right to consult their doctors and consultants on the slightest provocation. There is also a fear that under a so-called free service some patients may become too introspective about minor ailments and that the trammels of imaginary ills and anxieties may become self-nurtured to an unreasonable degree. No-one would decry the importance of minor disturbances of either the body or the mind, but factors which might tend to initiate, aggravate, or perpetuate them should be discouraged. The unnecessary direction of patients from doctor to doctor in a roundabout fashion may appeal to some of them, but others will be dissatisfied and lose confidence in the competency of their own medical attendant."

Dr. A. W. S. SICHEL, the retiring president for 1951–52, was present in Dublin, having made the journey from Cape Town for the second time in his year of office. Mr. J. W. TUDOR THOMAS, ophthalmic surgeon to the Royal Infirmary, Cardiff, was named president-elect of the association for 1953–54.

Representative Meeting

The representatives gathered in the Round Room of the Mansion House, close by St. Stephen's Green. They were officially welcomed to the city by Senator ANDREW CLARKIN, lord mayor of Dublin.

Dr. S. WAND (Birmingham) was in the chair. Dr. E. A. GREGG (chairman of council), in a preliminary examination of some of the events of the past year, congratulated the General Medical Services Committee, and particularly its late chairman, Dr. Wand, on the "magnificent work, splendidly done" which had led to the Danckwerts award.

REMUNERATION

Dr. WAND told the story of the Danckwerts award and of the Working Party set up to advise on the distribution of the central pool. The vindication of the profession's claim in open court would, he said, ensure a fair reward for the past four years of underpayment. There were good grounds for claiming that the betterment factor of 100%, applied in the award to the year 1951, was too low. The committee inferred from the terms of the award that a variable betterment factor should be applied in future years, but the Government did not agree. However, the committee thought that, as a contribution to national economy, higher figures should not be urged. Dr. Wand told the meeting that the question of income-tax on arrears had been settled. The arrears will be treated for tax purposes as four separate annual sums and not as a single sum taxable in the year of payment. Any additional payments to assistants made for services in the past four years as a result of the award would be allowed as expenses in assessing tax, and Dr. Wand hoped that principals would consider making such payments. He thought that the Commissioners of Inland Revenue had been very fair. The increase in the central pool for 1952–53 should be reflected in payments to practitioners in September next, when the increase due for the first quarter of the current financial year will be made. The second quarter's increase will come with the December payment, and the other two quarters will be covered in March of next year.

Turning to the proposals of the Working Party, Dr. Wand said that they had tried to encourage the entry of the young doctor into general practice by the Initial Practice Allowance. Moreover the loaded capitation fee would make established practitioners look more readily for partners. He thought that the decision to fix the loaded capitation fee on patients from 500 to 1500 was the right one; for below 500 the new doctor had the Initial Practice Allowance to help him. Some doctors' lists remained around 1200 from their own choosing; perhaps they had other sources of income or felt that they could provide a better service for fewer patients. But if most doctors decided to do a first-class job for 1200 patients, there would be a lot of work for the others.

The council recommended the meeting to endorse the resolutions on the Working Party's report adopted by the special conference of representatives of local medical committees on June 26.[1]

Dr. A. C. E. BREACH (Orpington) feared that the Working Party's report brought nearer the danger of a whole-time salaried service. Some doctors would be worse off, and he foresaw a new depressed class of doctors. Dr. WAND replied that nothing would be accepted that might lead headlong to a salaried service. Summing up, he thought that every practitioner depending mainly on N.H.S. practice for his living would be looked after by the Working Party's arrangements. The recommendations of the council were carried.

DISCIPLINARY ACTION

Representatives were concerned at the possibility of a doctor's name being removed from an executive council's list for an offence against the so-called spirit of the N.H.S. Act, an offence which did not involve any breach of his terms of contract. A motion by Dr. W. O'CALLAGHAN (Manchester) opposing such an action was carried, but only after Dr. F. GRAY (London) had warned the meeting that by doing so it would be enlarging the penalty for such offences, not diminishing it. Did representatives want all disciplinary cases that did not involve a formal breach of contract to be referred to the General Medical Council? It seemed from the mood of the meeting that they did. Dr. H. GUY DAIN (Birmingham) declared that it was quite improper that a doctor could be penalised in this way for other than a technical breach of contract. Dr. A. Talbot Rogers (Bromley), the new chairman of the General Medical Services Committee, said that counsel's advice was being taken on this point, and that when their case was ready the committee would speak to the Minister.

---

[1] See *Lancet*, July 5, 1952, p. 27.

PATIENTS' COMPLAINTS

Dr. J. W. McCarthy (Hendon) moved that every patient who complained against a doctor to an executive council should be required to deposit £2 with the clerk of the council as a token of good faith, and that should he fail to establish his complaint, or should it prove to be frivolous or vexatious, then the money could be made forfeit. He thought that a deterrent of this kind was badly needed. An amendment by the East Kent division sought to impose forfeiture only if the complaint was ruled to be "frivolous or vexatious." The meeting was not altogether happy about this idea, and a second amendment by Dr. Breach found support. He proposed that the patient should make a statutory declaration of the substance of his complaint, and that no disciplinary action of any kind should be started until such a declaration had been received by the executive council. Dr. Talbot Rogers thought that the type of patient most likely to make complaints of this kind would not be deterred by a statutory declaration. The East Kent amendment was agreed to, and the amended motion, together with Dr. Breach's amendment, was passed back to the council for consideration by their subcommittee, which, under the chairmanship of Dr. Dain, is already preparing a report on the working of the Tribunal and the medical service committees.

PREREGISTRATION YEAR

Referring to the terms of the Medical Act, 1950, Dr. J. A. Gorsky (Westminster) proposed that a period of six months in general practice should be accepted as one of the appointments qualifying for full registration. The matter was eventually referred to the council.

SPECIAL OBSTETRICAL LIST

An abrupt motion, brought from Gateshead by Dr. J. C. Arthur, asked that the special obstetrical list be abolished; and it was as abruptly and rather surprisingly carried. Opinion was evenly balanced: there were those who felt with Dr. Arthur that the list should go, in acknowledgment of the right and competence of all practitioners to do obstetrics; and there were others who agreed with Dr. F. Gray that its abolition would encourage further intervention by those who sought to take midwifery out of the practitioners' hands altogether. Dr. Talbot Rogers favoured its retention, for the signs as he read them suggested that a modus vivendi between the obstetricians and the practitioners would soon be reached.

EVIDENCE ON MARRIAGE AND DIVORCE

The agenda contained 21 amendments to the motion by the chairman of council to approve the memorandum, prepared by a special committee set up by the council, which was submitted in evidence to the Royal Commission on Marriage and Divorce. Most of these amendments criticised the council's action in submitting the memorandum without first referring it to the divisions and branches of the association. Dr. Gregg announced that the council had decided to ask permission to withdraw the motion, and that it would ask to have the memorandum removed from the evidence before the Royal Commission.

FILLING OF PRACTICE VACANCIES

There was much dissatisfaction with the present method of filling a vacant practice. Dr. W. M. C. Hallinan (Lewisham) pointed out how a small-list practice could dwindle alarmingly while the executive council's machinery was trying to get into top gear, which it seldom reached. He suggested that a register be kept of the names of doctors in a council's area who were prepared to fill vacancies; by this means the usual delay of many weeks could be reduced. This suggestion was generally popular, though Mr. J. E. Purves (Bromley) feared that it might give the executive council another chain with which to bind the doctor. The matter was referred for the attention of the council. The General Medical Services Committee will soon be able to give the results of its inquiries on this subject.

PRESCRIPTION CHARGES

The debate on the 1*s.* charge suddenly collapsed when the meeting unexpectedly decided that it would pass to the next business. But Dr. W. N. Leak (mid-Cheshire) did have time to say that he thought the charge would do little to discourage the scrounger, who still appreciated the bargain of getting 5*s.* worth of goods for 1*s.* However, representatives later considered that they had been too hasty, and decided to give the rural practitioners a hearing. Dr. H. H. Goodman (Newcastle upon Tyne) declared that the collection of the shillings by the country doctors was impracticable and iniquitous, and that it should not be asked of them. There were inevitable losses to the doctor, and it was a laborious business making sure that patients paid. Dr. Talbot Rogers observed that the method of collection by stamps had been the idea of a rural practitioner; it was certainly a big improvement, he said, on the Ministry's first proposals, which would have meant collecting cash and accepting a reduced dispensing capitation fee. He thought the scheme worked as well as could be expected, and a number of rural practitioners later agreed with him. Dr. Talbot Rogers told how, with representatives of the Rural Practitioners' Committee, Dr. Wand and he had vigorously opposed the charge before the Minister. It had become clear to them that an inflexible decision had been taken by high Government authority, and they were obliged to accept such concessions as they could get. The Newcastle motion to stop the collection of the charge by rural doctors was defeated.

VACCINATION

The meeting deplored the complacent attitude of the Ministry towards its inadequate propaganda about infectious diseases and especially about vaccination. Dr. N. J. Cochran (Burton on Trent) foresaw a panic over smallpox in another 20 years if the present tendency continued.

TRAINEE ASSISTANTS

Dr. Barbara Woodhouse (Harrow) thought that the trainee-assistant scheme was open to abuse in two ways: the trainee might desert general practice after his period of training; and the training doctor might use it to get a cheap assistant. Moreover the scheme was a waste of public money, for surely any principal who wanted a good assistant should be prepared to teach him without payment. The six months in general practice suggested for the preregistration year might make a more acceptable alternative to the scheme. Dr. H. S. Howie Wood (Isle of Wight) disagreed; he had found that a young doctor in the practice gave a stimulus to the work of the older man, a stimulus that many established practitioners would not receive but for the trainee scheme. Mr. E. E. T. Taylor (Northamptonshire) criticised the scheme for subsidising the teacher. An assistant is an asset, not a liability. The intelligence of young doctors was underestimated; they were quite capable of making sound practitioners without the formal instruction required by the scheme. Dr. R. M. S. McConaghey (Torquay) counted the scheme as one of the few really statesmanlike features of the health service. It did not really matter if the trainee left general practice in the end; he could not fail to be a better doctor in any branch of medicine after his year as an assistant. The Harrow motion that the scheme be abolished was defeated.

REGISTRARS

A general practitioner, Dr. J. L. McCallum (Westminster), pleaded the case of the senior registrars who may shortly lose their posts. They feel, he said, that few are interested in their grave difficulties, and that they would be better off under a full-time salaried service. The numbers involved are not so great as was at first feared, for some concessions have been gained; but perhaps 300 men, most of them between 35 and 45, are faced with the prospect of having to find work outside the hospital service. He asked the meeting to say that it considered that the Ministry of Health was responsible for finding them other employment. Dr. T. Rowland Hill (London), chairman of the Central Consultants and Specialists Committee, said that they had been fighting a continuous battle for the registrars, and though the position for many was still anxious the acute crisis had been relieved. Dr. Gorsky thought the battle had not been waged hard enough and he asked for an immediate increase in the registrar establishment. Mr. H. H. Langston (Winchester) could only see a solution to the problem if the consultant establishment was raised as well. At the division Dr. McCallum won his point.

S.H.M.O.S

Many representatives thought poorly of the Ministry's attitude towards the senior hospital medical officers. The Ministry had carried out its promise to review the status of all S.H.M.O.s in the latter half of 1951, but Dr. J. C. McMaster (West Somerset) knew that the S.H.M.O. group still included men with higher qualifications and years of experience who were being paid at a parsimonious rate. He thought that the grading committees should contain more general practitioners—not less than 20%. Dr. K. C. Bailey (West Somerset) condemned the S.H.M.O. idea as a mistake from the start; and the meeting went with him as far as to agree that all such posts in hospital establishments should be reviewed as a matter of urgency. Another source of annoyance was the way in which some newly graded consultants found their salaries unchanged because they were occupying posts graded as S.H.M.O. The Central Consultants and Specialists Committee did not feel that this circumstance could be challenged, provided the post was correctly graded. The meeting did not think that a grading committee should be influenced by whether or not the person under review was in general practice.

THE G.P. AND THE HOSPITAL

Mr. A. Staveley Gough (Watford) introduced his committee's report on the association of the general practitioner with hospital work. He hoped that it would help to reunite the practitioner with the hospital, from which the N.H.S. Act had divorced him. The meeting accepted the council's recommendations based on the report. The gist of these was:

(1) That the smaller cottage and G.P. hospitals be returned to the practitioner, and that certain wards in all other general hospitals be set aside for the treatment of patients by G.P.s.

(2) That part-time clinical assistantships be set up. Firstly, honorary clinical assistants could spend short periods in two or more special departments to widen their knowledge generally. Secondly, clinical assistants should be appointed for two years or so in a particular special department to enable the practitioner to gain some part of the experience necessary to become recognised in that specialty. These posts would be part of the hospital establishment, they would have definite responsibilities, and they would be paid. Thirdly, senior clinical assistantships should be offered to G.P.s who have adequate experience in a particular specialty, and who preferably have a higher qualification. They would help the consultant by doing work of a non-consultant nature. These appointments should be for regular weekly sessions and should be paid on this basis.

(3) That, particularly in rural areas, the appointment of part-time G.P.-consultants be continued.

(4) That G.P.s be given the opportunity for consultation on their own patients in hospital, and the right to attend ward-rounds and clinical and scientific meetings.

RETIRING AGE FOR CONSULTANTS

An amendment was passed calling for the compulsory retirement of consultants at 65 to be abandoned, and saying that this retirement was contrary to national policy in the economic crisis.

REGIONAL HOSPITAL BOARDS

Dr. J. E. Thomas (North Glamorgan) proposed the abolition of the regional hospital boards, and the vesting of their power in the local hospital management committees. The lack of interest shown by the boards and their annoying interference were, he said, a constant source of irritation. Dr. Rowland Hill was sure that the motion would defeat its own ends and increase the danger of stricter Ministerial control. They all wanted more freedom but this was not the way to get it. The motion was heavily defeated.

PROFESSIONAL SECRECY

The meeting disagreed with a recommendation of the council which would have modified the association's policy of absolute professional secrecy by allowing a doctor to speak when it became his moral or social duty to do so for the protection of innocent persons, and when the patient refused to act himself on the proper advice of the doctor. Dr. Robert Forbes, moving the adoption of this recommendation, emphasised that it did not seek in any way to weaken the bond of professional secrecy, but to provide for those cases in which the silence of absolute secrecy might bring harm to doctor, patient, or an innocent third party. Dr. Ffrangcon Roberts (Cambridge) regretted that as society advanced it became more and more menaced by the individual, and he deplored any move to change the attitude of the profession towards secrecy. Dr. Howie Wood thought that the recommendation would certainly be misinterpreted by the public and that it would lower the profession in public esteem. Dr. Gorsky saw no harm in the suggestion; for there were already lawful excuses which freed a doctor from his legal bond of secrecy, and there had been no public objection to such excuses. An amendment was passed removing the modifying words from the recommendation.

CIVIL SERVICE MEDICAL OFFICERS

Dr. Gregg announced that the Treasury had declined arbitration on the pay of doctors in the Civil Service. The association's request to reopen discussions in the light of the Danckwerts award had been unsatisfactorily answered. The Treasury had undertaken to review the new scale of salaries after a trial period. What this meant, said Dr. Gregg, was that the Treasury sought an opportunity to engage doctors on their own terms. The council had decided not to accept further advertisements of Civil Service medical posts for the *British Medical Journal* until a more satisfactory answer was given. The meeting unanimously approved this action.

JOINT MEETING OF ORTHOPÆDIC ASSOCIATIONS

A JOINT meeting of the orthopædic associations of the English-speaking world was held in London from June 30 to July 4. This congress was opened by H.M. Queen ELIZABETH the Queen Mother, who presented jewels of office, the gift of the British Orthopædic Association, to the presidents of the visiting associations from the United States, Canada, Australia, New Zealand, and South Africa. During the week there were demonstrations at London hospitals and many social events; and at the close visitors dispersed to visit provincial orthopædic centres.

At the congress dinner on July 3, attended by some 800 people, Sir HARRY PLATT, speaking of The Guests, welcomed particularly the representatives of the Brazilian, Dutch, Swedish, Portuguese, and other orthopædic associations, which if not English-speaking were English-reading and English-writing. Mr. IAIN MACLEOD, the Minister of Health, who responded, said that the link between so many participants of different country, politics, colour, and religion was that they really cared that there are sick and broken people. Dr. FREMONT CHANDLER, in proposing the toast of Orthopædic Surgery, spoke of the practical usefulness of the conference, and Sir REGINALD WATSON-JONES, the chairman, described it as a great event in the history of orthopædics. He hoped, incidentally, that on their visits to other parts of England, and to Scotland, Ireland, and Wales, the guests from abroad would take the opportunity of seeing to what extent the medical profession has become regimented. "We may not think much of our head gardeners," he remarked, "but at least they have not pulled up the unofficial English rose and planted rows of tulips." The conference had, he believed, shown that what holds together the Commonwealth and the United States is the pursuit of truth with no political bias.

The final toast, The English Language, was proposed by the MARQUESS OF READING, who quoted Bismarck's saying that the most important thing in the world is that the people of America speak English. Today Bismarck might say that the most important thing is that the English peoples speak American; but, after all, language was a living growth, and even the well of English undefiled might be the purer for a few tablets of American chlorine. We might be a poor country but we had a rich language: indeed, he regarded the 13 volumes of the *Oxford Dictionary* as a sort of linguistic Fort Knox in which is stored away—unseen, unused—the wealth of the English-speaking world. Basic, or debased, English might help the foreigner; but English without effort would never do for Englishmen. We had a language rich and subtle, resonant and strong: let us not condemn it to anæmia. Lord Justice BIRKETT, responding, said that English, with its flexibility and its words from every language under the sun, can deal with every situation. He agreed that it should not be afraid of importations, and he acknowledged our debt to America for such expressive inventions as sobstuff, sky pilot, highbrow, tenderfoot, and lounge lizard. But with the vitality of living speech we must seek also lucidity and grace—the one to make our thoughts plain, the other to make them memorable. Illustrating from Shakespeare what C. E. Montague called the "glamorous prestige of words in high company," he described it as our duty to welcome every importation that will live by its vitality, but also to regard ourselves as trustees. The English tongue was one of the bonds between the nations that use it; and in such bonds, he felt, lies the chief hope of the world.

Some of the papers read at the congress are summarised below.

Traumatic Dislocation of the Hip

Mr. E. A. NICOLL (Mansfield) said that in 144 cases of traumatic dislocation of the hip the incidence of aseptic necrosis of the femoral head was 10%. If the incidence reported from other sources varied, this was because necrosis was often confused with traumatic arthritis. The two conditions were very different. Necrosis was a vicious process; radiographic evidence, always present within two years of injury, preceded clinical features. Traumatic arthritis was a common, relatively benign complication of later development and slower course. Necrosis was commoner in children than in adults because there was absolutely no anastomosis across the epiphyseal cartilage-plate to make up for the interference with the blood-supply to the femoral head caused by retinacular damage. It might therefore be reasonable to carry out prophylactic drilling of the cartilage-plate after dislocation in childhood, but if so there was no point in blocking the new channels with bone grafts. Half the cases of necrosis were associated with delayed reduction or repeated attempts at reduction, so early recognition and gentle management were obviously essential. Premature weight-bearing was also dangerous; 20% of patients allowed to take weight within a month of injury developed necrosis, whereas the incidence was only $7^{1}/_{2}$% when walking was delayed. But even prolonged abstention from weight-bearing would not facilitate reconstruction of a normal head, once necrosis was established, by creeping substitution; the revivification process was too slow to prevent cartilage degeneration and massive collapse. The over-all incidence of necrosis was not high enough to justify routine prohibition of weight-bearing for more than eight weeks; but every case must be examined radiographically every three months for two years. If radiographic evidence were seen management was a difficult problem, for disability might be trivial despite the most alarming appearances. Of 15 cases of necrosis only 6 required operation (2 arthrodeses and 4 displacement osteotomies); the remaining patients had trivial symptoms and were all working.

Dr. MARCUS J. STEWART (Memphis), from an experience of 128 cases of dislocation and fracture-dislocation of the hip, did not believe that age, method of fixation, or time of weight-bearing had any influence on the outcome. The important factors were the severity of the initial trauma and delay in reduction. Because the urgency of reduction in determining the quality of the result was to be reckoned in hours, dislocation was more of an emergency than many a compound fracture or abdominal condition. But, quite apart from vascular disturbance, an important cause of necrosis was the molecular change in structure of the head produced by the impact; the fact that the time of onset of necrosis was exactly the same—17 months—whether open or closed methods of reduction were employed suggested that the die was cast for or against necrosis at the time of injury. When there was coincident sciatic nerve injury and the radiograph showed large separated bone fragments exploration should be done; for the nerve might be transfixed.

In the discussion of these two papers Dr. PAUL B. MAGNUSON (Washington) confirmed that minimal clinical features might accompany severe radiographic changes of necrosis; the plane of flexion-extension at the hip habitually used by the patient could be smooth and painless, though the surgeon was able to demonstrate that other ranges were blocked and painful. Revascularisation of a dead head could be accelerated by partial resection of the subjacent neck, bringing up the shaft and transplanting the great trochanter downwards.

Mr. JAMES PATRICK (Lanarkshire) thought a clear distinction between necrosis and arthritis was not made sufficiently often. The stigma of necrosis was collapse of the head, and this might occur abruptly after months of apparent radiographic normality.

Dr. J. M. EDELSTEIN (Johannesburg) agreed that the initial damage to the head was often concealed and therefore an unfavourable prognosis could sometimes be made, but never a favourable one. The only conceivable short cut to good function in severe established necrosis might be the use of a prosthesis for the femoral head.

Mr. K. H. Pridie (Bristol) admitted no essential distinction between necrosis and arthritis. Massive necrosis was recognisable as such; but minor focal necrosis invisible in the radiograph could initiate spreading reactive changes and degeneration of the overlying cartilage which was in fact post-traumatic arthritis.

The Arthritic Hip

Dr. Frank Stinchfield (New York) opened a discussion on the indications for the various operations for osteo-arthritis of the hip. Sound arthrodesis was painless and satisfactory; and he aimed to obtain it by combining joint erasion, metallic internal fixation, and an ilio-trochanteric bone graft: some 20% of cases developed pseudarthrosis, but half of these were satisfactorily fused at a second operation. Arthrodesis was preferable in young patients, in manual labourers, in unilateral disease, in old septic hips, and when patients were uncoöperative. Cup arthroplasty had not given dependably good results; some limp was universal, and the range of movement tended to diminish after the fourth year. It was more suitable for the middle-aged sedentary person with bilateral disease who could be relied on to work almost religiously at postoperative exercises. Coxa valga and a shallow acetabulum were also points in favour of arthroplasty—an operation which did not preclude subsequent revision or arthrodesis. Old patients did not stand cup arthroplasty well, and here the use of the Judet prosthesis was better. This procedure was easier and less shocking, with rapid reablement, and was valuable for aseptic necrosis; but it had no place with young patients and the late results were unknown.

In discussion, Mr. Alexander Law (London) thought that the high incidence of pseudarthrosis and backache after fusion favoured arthroplasty, which was no more likely than arthrodesis to cause old sepsis to flare up. His impression was that the Judet operation gave a very mobile hip initially which subsequently tightened up, and he questioned the durability of the prosthesis if used for young patients. Follow-up of a series of bilateral cases treated by insertion of a cup on one side and an acrylic head on the other would be very instructive.

Mr. John Charnley (Manchester) described his technique for arthrodesis of the hip, in which a central dislocation was produced, the femoral head entering the pelvis. The resulting bone block made rotation and late adduction deformity impossible, so there was no need to fix the knee postoperatively. Even a fibrous ankylosis was sound under these circumstances, but he now made bony fusion certain by applying spring compression via a transfixing screw. All his patients had clinical fusion at six weeks and were back at work in three to four months—a remarkable record. The balance of opinion against fusion was due only to the irregularity of its success in the past; when bony ankylosis could be routinely produced within a few months without secondary back or knee strain the indications for arthroplasty would be fewer.

Dr. Arthur Steindler (Iowa) was opposed to any irreversible operation on the hip-joint unless the compelling symptom of pain had been carefully analysed as to its source. Pain of purely synovial origin could clear up if the synovial pathology were reversible, as it often was.

Treatment of Tuberculous Hip

Mr. Thomas King (Melbourne) described the advantages of allowing adduction deformity to occur during conservative treatment of tuberculous hips in adults, and then performing Brittain's ischiofemoral arthrodesis. The operation was much easier with a short ischiofemoral interval, and a stout graft (he preferred the fibula) could be used without fear of breakage; he added an arthrodesis nail fixed to a plate on the outer aspect of the femur so as to dispense with plaster fixation.

In a written comment Mr. H. A. Brittain (Norwich) said that he disliked the use of metal in tuberculous joints, could see no need for a nail and plate when the essence of his operation was osteotomy-displacement without fixation, found his original tibial graft more easily vascularised than a portion of fibula, and noted that extreme adduction was usually associated with enough flexion to bring the sciatic nerve dangerously forward into the operation field.

Dr. D. M. Bosworth (New York) did an arthrodesis as soon as he made the diagnosis, so there was no time for adduction to develop; nail fixation could carry tuberculosis into the pelvis. Late adduction was only compatible with ischiofemoral fusion when the head and neck had not been destroyed.

Mr. G. Parker (Middlesbrough) had for several years been allowing adduction to occur and performing Brittain's operation in those tuberculous hips in children likely to require fusion, with excellent results. But Mr. Michael Wilkinson (Black Notley) deplored any routine adoption of such a programme; for, in his hands, chemotherapy combined with subtotal synovectomy in early cases gave mobile hips with good function; and the opportunity to do this, once lost, was irretrievable.

Osteoid Osteoma

Mr. John Golding (London) reviewed the characteristic features of osteoid osteoma. Continuous boring pain might be accompanied by local swelling, and operation revealed the cherry-red, highly vascular tumour lying within sclerosed bone. The tibia was the commonest site, but obscure lesions in the spine or hip made diagnosis difficult and radiographic evidence was not always available. The typical widespread regional sclerosis was a reaction to the vascularity of the tumour of the kind often seen in relation to angiomata of bone. The disease was self-limiting after a course of several years; so, while easily accessible lesions should be removed, radiotherapy should be employed for other sites rather than attempted radical extirpation.

Dr. H. H. Young (Rochester, Minnesota) said that femoral lesions could cause sciatica simulating disc prolapse. Pain was too severe to justify waiting for spontaneous regression. Dr. J. R. Moore (Philadelphia) classified the disease into cortical, cancellous, and subperiosteal varieties; juxta-articular lesions could mimic acute arthritis.

Mechanism of Gait

Prof. John Saunders (San Francisco) gave an account of an investigation into the mechanics of normal gait. Human locomotion was an exceedingly complex process to analyse; Nature's object was the translation of the body through space with the least expenditure of energy, its centre of gravity describing a sinusoidal pathway of low amplitude with a horizontal as well as a vertical excursion, and making a figure of eight in two dimensions and a spiral curve in three. The major determinants of normal gait could be deduced by comparing human progression with that of a simple compass model. The centre of gravity of such a model passed through a series of high arcs with sharp deflections and extravagant energy expenditure. The body modified this by means of pelvic rotation, which reduced the required range of flexion and extension at the hip; by pelvic tilt; by knee flexion on the weight-bearing side between the extension which began and ended the stance phase of gait; by providing subsidiary arcs at forefoot, heel, and knee; and, finally, in the horizontal plane, it limited the wide sweep of the compass model by means of normal femorotibial angulation. All these devices combined to make the legs $2^1/_2$ times longer functionally than they were in reality, and to limit the excursion of the centre of gravity to the confines of a 2-in. cube.

Dr. VERNE T. INMAN (San Francisco), collaborator in this research, had studied the energy expended in raising and lowering the centre of gravity during locomotion by means of force plates—horizontal platforms supported on bronze pillars—the deformation of which was electrically recorded. The resulting oscillograms were obtainable from one or both legs and recorded both vertical stress and lateral shear. Force-plate studies confirmed the sinusoidal path of the centre of gravity and demonstrated the extra expenditure of energy necessitated by pathological conditions. High heels, like fused ankles, caused little change, though accompanied by increased knee flexion and pelvic roll; but the fixed knee required more energy output. The below-knee amputee was relatively normal from this point of view, but a thigh amputation required 27% greater energy expenditure; such a patient in effect walked 5 yards to another man's 4, and this must be considered in supplying an artificial limb to a cardiovascular invalid after amputation. Energy was also expended in walking in producing oscillation of the legs, two-thirds deriving from the foot and ankle and one-third from the hip mechanism; the knee merely absorbed and dissipated energy, and patients with a fixed knee or long leg plaster had a greater hip excursion than normal.

In discussion, Mr. PHILIP WILES (London) said that such fundamental studies might help in assessing the value of a proposed operation such as arthrodesis. Dr. BECKETT HOWORTH (Connecticut) said that the higher the heel the nearer was the functional approximation to the Symes amputation because of obliteration of ankle function and shortening of forefoot leverage. The quadriceps mechanism was the first to fail in leg strain.

Traumatic Paraplegia

Mr. F. HOLDSWORTH (Sheffield) described his management of traumatic paraplegia, based on experience with 68 patients with lumbodorsal fracture-dislocation. There had been too much pessimism about prognosis in these cases. The dictum that complete motor and sensory loss for forty-eight hours indicated irreversible damage applied only to the cord; but at the common level of injury around the lumbodorsal junction the cord contained only sacral segments and the lumbar elements were present as roots, which could recover. Here any retained power in the legs was an index, not of a spared cord, but of root escape; and it was vital to encourage root recovery by reducing and fixing the spine lesion. Return of control of the hips would allow relatively normal walking compared with the tripod gait of the complete paraplegic. Treatment of the fracture was also essential, because angulation interfered with balance when reablement began. Radiography was not always helpful in assessing the displacement obtaining at the time of injury, or the potential instability during nursing. Gross crush of a vertebral body with facets intact was a stable lesion and no operation was indicated, even for partial cord damage unless this was progressive. The common cause of unstable fracture-dislocation with paraplegia was torsion plus flexion, which disrupted the facets, produced a horizontal slice fracture of the lower vertebral body, and was recognisable clinically by a gap between the spinous processes and a local hæmatoma. This lesion was so unstable that open operation and internal fixation by two long plates screwed to the spinous processes was required as an emergency. It was then possible to turn the patient two-hourly; plaster beds were unnecessary, and there were no bedsores, myositis ossificans, or stiff joints. In 47 patients treated from the outset there had been not one bedsore; and these patients walked at six months and left hospital in ten months, 30 having been operated on. But not 1 of 21 patients admitted late was out of hospital in under two years, and these suffered the complications of classical management. An indwelling catheter was far better than suprapubic drainage.

Mr. NICOLL said that Mr. Holdsworth's policy offered the only hope to these patients, though the operation was not always simple. Colonel A. W. SPITTLER (Washington) used the Stryker frame and Foster bed to facilitate turning: if operation were done he obtained fusion by bone grafting.

Dr. LUDWIG GUTTMANN's experience with 800 paraplegics at the Ministry of Pensions Hospital, Stoke Mandeville, had led him also to abandon the plaster bed and suprapubic drainage; but he did not feel that early operation necessarily guaranteed any recovery of function. Reablement began when the patient was first seen; even a patient completely paraplegic from waist down should be at work in seven to twelve months. Dr. PHILIP WILSON (New York) doubted the security of metal-plate fixation and preferred bone grafting; but Sir REGINALD WATSON-JONES (London) accepted Holdsworth's thesis because fixation for nursing purposes was required only for the few weeks before the spine acquired its own stability.

Fractures of Cervical Spine

Dr. WILLIAM ROGERS (Boston) described his experience with 77 cases of cervical fracture-dislocation. Of the 15 deaths, 12 were associated with cord injury and 3 were due to pulmonary embolism. Anterior dislocation was the usual cause of quadriplegia, but the severity of the cord injury was not commensurate with the degree of displacement. The most dangerous group were the old people with stiff arthritic necks, and there were some cases of hyperextension injury; paralysis without radiographic evidence of fracture-dislocation was due to disc retropulsion or to hyperextension with infolding of a ligamentum flavum. Hyperflexion dislocation could occur with complete rupture of all ligaments and yet undergo complete spontaneous reduction. Only a minority of cervical fracture-dislocations escaped cord injury; but in 10% of cases this was acquired *after* injury during transit to hospital, or actually in hospital from careless handling or such manœuvres as halter traction or laryngoscopic intubation. When cord damage came on immediately, death was inevitable. For the emergency nothing was better than the simple turnbuckle distraction brace, based on shoulders, neck, and occiput; later, skull traction produced complete reduction in most cases without any hazard to the cord. Most of the failures with skull traction were in cases of posterior displacement and unilateral rotary dislocation.

Mr. V. H. ELLIS (London) agreed that patients who had succeeded in breaking their necks without cord damage ran a grave risk of acquiring the latter during treatment. Once skull traction was in place the patient was safe; and because the spine remained unstable he wired the spinous processes and performed bone grafting at the same time. Dr. T. C. THOMPSON (New York) applied skull traction by means of malar fish-hooks, and such traction could be weighted unequally to correct lateral shift.

Adrenocortical Function

Dr. PHILIP WILSON (New York) described a study of adrenocortical response in orthopædic patients, as shown by eosinophil-counts. Adrenocortical function must affect the outcome of many procedures, and good results were often attributed to technique which were really the outcome of the non-specific stimulus to the pituitary-adrenal axis. Stress eosinopenia was common in patients admitted with injuries, infections, and acute low-back strain; it was also seen with bone tumours. It was not seen in patients admitted for elective surgery. Post-operatively, there was immediate profound eosinopenia (which did not occur during the anæsthesia) followed by a rebound, sometimes above normal, on the second to fourth day; failure of this response indicated a dangerous lack of adrenocortical reserve. Protracted eosinopenia was associated with complications in recovery and was of some prognostic value.

Prof. J. Trueta (Oxford) welcomed this work as a corrective to the mechanical-mindedness of orthopædists; but eosinophil-counts were so variable that care was needed in their interpretation. Dr. Beverly Raney (North Carolina) wondered if the mechanism of eosinopenia was always the same, for there was some evidence that it could occur in adrenalectomised animals.

Changes in Lumbosacral Region

Dr. Ian MacNab (Toronto) gave an account of an investigation into the structural changes seen in a large number of lumbar spines post mortem. The intervertebral discs were maximally developed by the end of the second decade and thereafter aged and degenerated by inspissation and transformation of the ground substance into formed elements. The rate of senescence varied, and degeneration differed from normal ageing only in its prematurity and its possible association with trauma. The changes included radial posterior or posterolateral annulus tears; nuclear extrusion; multiple hæmorrhages giving a brown siderotic disc; or a massive single hæmorrhage into the nucleus. The entire disc might become soft and putty-like and extruded beyond the rim of the vertebral bodies by body-weight. Disc degeneration made segmental intervertebral movement lose its smoothness, and the axis of flexion-extension passed backwards to the small articulations, which suffered considerably, tending to subluxate in flexion and with an overriding of the facets which might allow the inferior articular process of one vertebra to wear a hole in the lamina below. Such overriding could also be associated with reversed spondylolisthesis of the upper centrum and with nerve-root pressure. The capsules of these small joints became fibrosed, chondrified, or ossified, and loose bodies in the joint cavities could lock the back in acute lumbago. The radiographic signs of late disc degeneration were obvious; at an earlier stage it was necessary to demonstrate abnormal mobility of the upper vertebral body in flexion and extension films. Disc degeneration was not necessarily accompanied by disc prolapse, though prolapse was always an incident in a degenerate disc. Degeneration was universal and gave rise to radiographic signs; prolapse was an accident in a few individuals and might have no radiographic features.

Mr. E. F. West (Adelaide) discussed the origin and treatment of spondylolisthesis. Trauma seemed a more likely cause than congenital ossification defects; and progressive displacement was probably rare because limited by ossification in the anterior bulge of the associated disc.

Discussing these two papers, Dr. J. A. Freiberg (Cincinnati) advised excision of thickened zygapophyseal joint-capsules at operation for sciatica, for they might be the sole cause of root pressure. It was difficult to reconcile the bulging disc of senile vertebral osteoporosis with the progressive inelasticity of disc degeneration. Mr. A. D. Eyre-Brook (Bristol) doubted the practical value of the numerous radiographic abnormalities of the lumbosacral region; clinical evidence should be the basis for operation for sciatica, and if no disc prolapse were found the intervertebral foramen must be explored.

Dr. Donald King (San Francisco) found anterior fusion with a tibial bone graft through an abdominal approach unsatisfactory in spondylolisthesis; the graft fractured where it traversed the avascular disc. But Prof. Merle d'Aubigné (Paris) was very happy with the abdominal operation; he replaced the disc with an iliac graft, transfixed the lumbosacral joint with a large screw, and allowed his patients up in two weeks without immobilisation. Mr. Norman Capener (Exeter) thought that spondylolisthesis might be sometimes due to stress fracture of the neural arch. Reduction of displacement was possible but this always recurred, even after grafting. Prof. Sten Friberg (Stockholm) said that the condition could be due to congenital deficiency, chronic strain, or acute trauma. Congenital causes certainly existed. The other two types were associated with an elongated or a ruptured isthmus respectively. Loss of elasticity was the essence of disc degeneration, and discography with opaque media showed this could begin in the 'teens.

The Ischæmic Hand

Dr. Sterling Bunnell (San Francisco) described the entity of local ischæmic contracture of the intrinsic muscles of the hand, due to swelling within tight plaster or vascular injury in the forearm. The intrinsic minus position of ordinary claw-hand was well known; but here there was an intrinsic plus position due to spasm or fibrosis of the small muscles, with metacarpophalangeal flexion and interphalangeal extension in the fingers and fixed adduction of the thumb. It might accompany Volkmann's contracture or occur independently, and when the metacarpophalangeal joints were fully extended passively the interphalangeal joints could not be flexed. The hand could not be opened for grasping. Prophylaxis consisted in avoiding further embarrassment of the circulation in the hand after injury. Treatment of the established condition was by forward stripping of the interossei along the metacarpals when the muscles had any residual function, so allowing them to lengthen; or, when they were fibrosed, tenotomising the lateral bands of the finger-joints. The thumb was dealt with by complete incision of the first cleft, stripping or excising contracted muscle and opening the first carpometacarpal joint; the functional position of opposition was maintained with an intermetacarpal bone graft threaded with a wire and the raw cleft lined with a free or pedicled skin graft.

Mr. Guy Pulvertaft (Derby) spoke of the need for prolonged after-treatment with this procedure, for there was a tendency to relapse and re-formation of the lateral bands. Splintage and elastic traction were essential.

Arthroplasty for Congenital Dislocation

Dr. Paul Colonna (Philadelphia) described the good results obtained over twenty years with his operation of capsular arthroplasty for congenital dislocation of the hip. His age-limits were 3–6 years for bilateral, and 3–8 years for single, cases. The femoral head must be brought right down by preliminary traction, a deep cup-(not saucer-)shaped acetabulum made at the original site, and the head placed therein with capsular interposition. For marked anteversion a supracondylar femoral osteotomy could be done subsequently. The false acetabulum was left alone and no shelf made; it filled in spontaneously over the years. Very occasionally a shelf was needed years later for instability.

Dr. Alexander Gibson (Winnipeg) discussed open reduction of congenitally dislocated hips via the posterolateral approach. Closed reduction was often satisfactory to patient and parents for some years, though the radiographs gave the surgeon little cause for complacency. His operation was less damaging than manipulation and so simple as to be the method of choice. The superior part of the capsule was incised transversely and the medial flap stripped with a thin layer of bone off the dorsum ilii down to the level of the true acetabulum. The femoral head was gently replaced and the medial capsular layer overlapped above the lateral layer, so obliterating the entry of the head into the joint diverticulum above; the osteogenic capsular flap contributed to the formation of a good roof without any necessity for a shelf.

In discussion, Sir **Harry Platt** (Manchester) said that open reduction could be used as an alternative to closed methods when concentric reduction was made difficult by soft-tissue anomalies or an over-large femoral head; but no reconstruction of the acetabulum was needed for these young children except the occasional making of a shelf. He was not convinced that operation should routinely replace closed reduction.

Mr. H. J. **Seddon** (London) wondered whether Dr. Colonna was using his procedure where other surgeons might perform simple open reduction, with or without acetabuloplasty. What was to be done with patients too old for capsular arthroplasty and too young for an adult type of procedure? Could a cup or prosthesis be seriously considered? He did Colonna's operation in this difficult age-group of 8–14 years, but with less satisfactory results; the hips were often very stiff but were at least in good position for subsequent arthrodesis or arthroplasty. Mr. J. B. **Colquhoun** (Melbourne) said that those who believed that a high proportion of cases could be reduced by manipulation reserved Colonna's operation for their failures, and it was not surprising that their results were worse than those of Colonna himself, with his more liberal indications.

Scoliosis

Dr. **John Cobb** (New York) discussed the selection of the fusion area in scoliosis. A mature massive fusion would maintain the stability of a corrected curve, but the operation was necessary in less than 5% of idiopathic scolioses. The ideal case was a single stable non-paralytic non-progressive curve in a patient over 15, in whom correction was desirable and possible. There was some confusion as to the meaning of correction, which applied to the angular deformity and did not mean straightening the whole curve. If, as was usual, the compensatory curves could not be corrected completely correction of the primary curve must not be complete and the accepted principle of always fusing between parallel lines was wrong. This was indicated when side-bending away from the primary convexity did not obliterate the secondary curves, and the area of fusion must be balanced against the residual uncorrectable angular deformity. When, on the other hand, maximum permissible correction of the primary curve was not obtainable, the fusion area might be extended beyond the parallel lines into the secondary curves themselves.

Mr. J. I. P. **James** (London) discussed prognosis in idiopathic scoliosis in relation to curve patterns and age of onset. Onset could be infantile, juvenile, or adolescent; and prognosis was worse the higher the apex of the curve.

The most benign pattern was *lumbar idiopathic scoliosis*, mainly of adolescent origin in girls. Severe angular deformity was seen in only 9%; and the clinical appearance was better than the radiograph suggested, the shoulders remaining level and the ribs unrotated. But late lumbar osteo-arthritis was the rule, all patients over 35 suffering pain.

The *primary thoracolumbar curve*, again mostly in adolescent girls, had its apex around T11–12. Severe deformity was now seen in a third of the cases and most patients had pain in adult life.

Thoracic idiopathic scoliosis was usually a right convexity with a variable apex between T6 and T10; two-thirds of the cases were severe, with marked rib rotation and shoulder asymmetry. The clinical appearance was worse than the radiograph, and an ugly deformity developed when the curve angle reached 70°. In this group the minimum final angulation was 50° and the maximum 150°. Half the cases of adolescent onset and 90% of those of juvenile onset developed severe curves.

Infantile idiopathic thoracic scoliosis was exceptional in being mostly in males and usually left-sided. It invariably became severe with growth and little could be done to prevent this.

Combined lumbar and thoracic scoliosis comprised two primary and two secondary curves—the only pattern with four instead of three curves in all. It was almost as benign as lumbar idiopathic scoliosis.

In treatment, operation was rarely required for lumbar and combined curves, but fusion was necessary for severe pain and deformity in thoracic cases. Mr. James had not operated on children under 10, but this might prove desirable in some cases.

In discussion, Dr. **Claude Lambert** (Chicago) said that such a classification was not always helpful in deciding treatment. He did not agree that lumbar curves never needed fusing, and operation would be indicated for severe progressive deformity even in children under 10. Mr. H. **Osmond-Clarke** (London) spoke of the possibility of dealing with scoliosis by controlling vertebral epiphyseal growth.

Sympathectomy for Causalgia

Mr. **Roland Barnes** (Glasgow) spoke on causalgia after injury to major peripheral nerves. The spontaneous severe persistent burning pain spread beyond the anatomical territory of the nerve concerned, was exacerbated by physical and emotional stimuli, and was accompanied by trophic changes. There were good reasons for not believing it to be mediated by afferent sympathetic pathways despite the relief afforded by sympathectomy; nor was there such persistent peripheral vasoconstriction as to support Lewis's suggestion that sympathectomy afforded relief by securing vasodilatation. Benefit must be due to interruption of efferent sympathetic fibres which stimulated the nerve-trunk through an artificial synapse or short-circuit at the site of injury, centrifugal impulses causing the peripheral vascular disturbance and centripetal ones the pain. Only this view explained the relief which might follow nerve-block distal to the lesion, and the rarity of causalgia after complete nerve section. In the arm, preganglionic section was effective and postganglionic operation the usual cause of relapse; lumbar sympathectomy was necessarily mainly preganglionic and the results satisfactory.

Mr. D. **Lloyd Griffiths** (Manchester) commented that causalgia did, rarely, occur after complete nerve section and in the phantom limb after amputation. Peripheral short-circuits must not be confused with true synapses. If sympathectomy did not relieve causalgia it was because the operation had not been adequate. But Dr. I. W. **Nachlas** (Baltimore) had found that the most extensive sympathectomy might fail to relieve. Not all cases were the same; the skin might be warm or cold, the bone texture normal or porotic.

Skeletal Tuberculosis Treated by Isoniazid

Dr. **David Bosworth** (New York) gave a breath-taking account of his experience in treating skeletal tuberculosis with *isoniazid (isonicotinic acid hydrazide* and its isopropyl derivative). It was premature to speak with assurance after only eight months' acquaintance with these substances; but it was already clear that they could produce remarkable subsidence of fever, and also euphoria, weight gain, and relief of pain (the last often independently of any improvement in the local condition). Sinuses of long duration which had resisted streptomycin might heal in a couple of weeks, sometimes even while the patient was dying of tuberculosis. Though the drugs were certainly bacteriostatic, these rapid results suggested a possible action on mesodermal tissue, as distinct from a suppression of infection; and this was borne out by the benefit they gave in collagen diseases like lupus erythematosus. But there was no evidence that they had a cortisone-like action; eosinophil and ketosteroid studies did not support this view, nor indeed the remarkable tendency to wound healing. Meningeal and cutaneous tuberculosis responded favourably; and a non-specific improvement in pain and function was even seen with rapidly growing malignant tumours. Toxic manifestations with the isopropyl derivative included hepatitis and central-nervous system disturbance ushered in by clonus. The margin of safety in dosage was small; it was best to begin with a dose of 4 mg. per kg. body-weight, increase this until clonus developed, and then come down to a safe level.

In the discussion of this paper there was a general feeling that these drugs supplemented, but did not replace, surgery. Dr. Bosworth had made it clear, however, that patients could be made safe for surgery at a much earlier date than hitherto.

Orthopædic Manifestations of Leukæmia

Mr. D. LLOYD GRIFFITHS (Manchester) gave an account of the orthopædic manifestations of leukæmia, which seemed to be on the increase in childhood, where it was now the sixth commonest cause of death. When the early stages were aleukæmic, and when the presenting lesion was osseous, diagnosis was difficult without sternal puncture. The leading symptom might be backache, sciatica, limp, or paraplegia; so cases might be treated for months as tuberculous spines or instances of Perthes's disease before the situation became clear. Destructive (not osteolytic) changes were seen as translucent metaphyseal zones, as focal erosions, or as diffuse painful infiltrations; these changes might reflect an attempt at compensatory extension of red marrow. Extensive bone infarction could occur and would not necessarily show in the radiographs, since the disease inhibited the healing processes which demarcated infarcted areas. Other changes included sheath-like subperiosteal ossification and, usually in the vertebral bodies, massive sclerosis. Apparent remissions with anti-folic-acid drugs or A.C.T.H. were only temporary.

Mr. JACKSON BURROWS (London) remarked that the disease was sometimes confused with senile osteoporosis when it affected the spines of old people; but osteoporosis did not involve the hands or pelvis, and such odd points should arouse enough suspicion to justify sternal puncture.

M.B. Lpool, D.P.H., D.M.R.E.
RADIOLOGIST

W. S. TAYLOR
M.S.R.
SUPERINTENDENT RADIOGRAPHER

CENTRAL MIDDLESEX HOSPITAL, LONDON

THE National Health Service has removed the patient's concern about the cost of his treatment. Indeed, as a contributor intent on getting his money's worth, he may take a pride in the number and variety of tests and examinations carried out upon him, and he is often more impressed by the complexities of his investigation and treatment than by the result achieved. He may retain for years a feeling of satisfaction and self-importance arising from a complete overhaul, during which hardly any avenue has been left unexplored by "scope" or contrast medium. We have reached the stage when the good specialist may be defined as the doctor who knows when to stop. Investigations are not only unnecessarily wasteful but (even more important) they use materials which in these days are hard to obtain, such as chemicals, X-ray film, drugs, and dressings.

Radiological investigations are the most expensive commonly carried out in hospitals, and it seemed to us that all who ask for a radiological examination to be made ought to know what it costs in money and materials. Accordingly we surveyed the expenditure in our department for the year, April 1, 1950, to March 31, 1951. We did not include the costs of buildings, heating, lighting, water-supply, painting, and other expenses directly concerned with the structure of the department. Expenditure on these items is of course essential, but it was difficult for us to estimate the sums involved, especially in a department that had undergone only minor structural changes for many years.

TABLE I—EXAMINATIONS MADE IN 1950

THE WORK DONE

The department is a closed one, dealing only with patients from the different sections of an 800-bed regional hospital. In 1950, 25,000 patients were examined and the general scope of the work is set out in table I.

WHAT IT COST

Staff

The staff consists of a whole-time consultant radiologist, a senior registrar, and a registrar on the medical side; a superintendent radiographer, a senior radiographer, four junior radiographers, and a dark-room technician on the radiographic side; a clerical staff of four; two assistant nurses; two porters; and a cleaner. The pay-roll of these nineteen people comes to £11,760 (including superannuation and national insurance). About £100 was spent in arranging transport for radiographers on call after normal working hours.

Materials

During the year, approximately 58,000 films of various sizes were used, costing £6200. The cost of chemicals used in the dark-rooms was £373 for the year.

Contrast media were a fairly heavy item. Barium sulphate preparations for gastro-intestinal examinations cost £285. Diodone compound for pyelography, intracavitary radiography, salpingography, and arteriography cost £291. Iodised oil preparations, used almost entirely for bronchography, cost only £60. Pheniodol compounds for cholecystography cost £61. Smaller amounts of contrast media for other examinations cost £12.

Breakdowns

So far the expenditure was foreseeable. But in any radiological department mechanical breakdown of plant is fairly common.

Though the modern rotating anode tube may survive 30,000–40,000 exposures or even more, a breakdown, which means an expensive renewal, may be expected at any time after the lower figure has been passed, and there is always the possibility of it happening before. The makers usually guarantee a minimum of 20,000 exposures and will generally bear a proportion of the cost of replacement below this number.

X-ray rectifying valves are also expensive to renew, and in our experience valve failure in the four-valve X-ray set is 2–3 times more common than tube failure on the same set.

Mechanical breakdown is also not unusual. It can be reduced by regular inspection and overhaul but it cannot be avoided.

The cost of replacement and maintenance for the year, together with an additional rotating anode tube, was £1250.

Cassettes and intensifying screens in continuous use must be replaced, and additions are necessary where the work is increasing. These items accounted for £269 in the year. The cost of sundry items, including replacements of lead protective gloves, aprons, and film-markers, was £36.

Clerical and Nursing Section

Expenditure on the clerical side of the department was considerable. Additional filing accommodation for films cost £227, record-card filing accommodation £48, a lantern-slide cabinet £12 10*s*., and sundry other items, including viewing-boxes, brought the total cost of equipment in the offices to £392. Stationery, including record books and film envelopes, cost £413.

Syringes, instruments and similar expenses on the nursing side were estimated at £200.

Depreciation

X-ray equipment, like all complex electrical devices, has a comparatively short life. This can be prolonged by maintenance up to a point, but after some years it becomes increasingly unserviceable and progressively outdated in design and capacity. For the purposes of depreciation an arbitrary life of ten years was allowed to the X-ray sets themselves, and yearly depreciation calculated on the basis of a tenth of the estimated value. The figure arrived at was £1750 for the whole department.

The Total

The total cost of £23,453 incurred by the department in the year is summarised in table II.

TABLE II—ANALYSIS OF COST OF DEPARTMENT

Salaries and wages	£11,760
Transport cost	100
Cost of films	6200
„ „ chemicals	373
„ „ contrast media	709
Maintenance	1250
Cost of cassettes and screens	269
Sundry protective items	36
Clerical section	806
Nursing	200
Depreciation	1750
	£23,453

The department did bring a little revenue to the hospital. Old X-ray films sold at £61. The silver-recovery plant in the fixing tank brought in £26. The credit total was £87.

WHAT EACH EXAMINATION COSTS

The net cost of the department was thus about £23,400 for the year, and this did not include any allowance for essential services or structure.

If the cost of films, chemicals, and drugs (£7282) is deducted from the total, the remainder (£16,118) represents the basic cost of the department, an average of 13*s*. per patient. To obtain the cost of an examination, we have added to this basic cost the cost of the average amount of material used in the examination. Thus, a barium-meal examination that may need 3 sq. ft. of film costs 6*s*. 6*d*. for film, 2*s*. for contrast media, and a few pence for chemicals, plus the basic cost of 13*s*.—in all about 22*s*. On similar accounting a barium enema costs about 23*s*. 6*d*. An intravenous pyelogram costs 12*s*. for film, 4*s*. for an ampoule of contrast, a few pence for chemicals and the basic cost of 13*s*. making a total of about 29*s*. 6*d*. A chest film or a plain film of the abdomen costs 17*s*., a bronchogram about 30*s*., and a cerebral arteriogram (where perhaps six films of each side may be necessary and four ampoules of contrast media) about 50*s*. The cost of various examinations is given in table III.

TABLE III—COST OF VARIOUS EXAMINATIONS

Examination	*Cost*
Plain X ray of chest or abdomen	17*s*.
Postero-anterior and lateral chest	21*s*.
Bronchogram of both lungs	30*s*.
Intravenous pyelogram	29*s*. 6*d*.
Retrograde pyelogram	24*s*.
Barium meal	22*s*.
Barium enema	23*s*. 6*d*.
[illegible]	24*s*. 6*d*.
[illegible]	50*s*.
[illegible] spine and pelvis	21*s*.
„ „ whole spine	25*s*.
Dental radiograph	14*s*. 6*d*.

CONCLUSION

We have not tried to do more than get an idea of the expense of the investigations ordered so often in hospital. This will clearly vary a good deal from hospital to hospital. All that we can claim is that our estimates are those of a department where economy is practised as far as is consistent with a satisfactory standard of work. We do not suggest that the cost of an examination should deter a clinician from requesting it. But he ought always to consider whether it is reasonably likely to give him information which is of value and which cannot be obtained by less expensive means.

We wish to thank Mr. J. Collins, assistant secretary, The Central Middlesex Hospital, for making the necessary accounts readily available to us, and Dr. Horace Joules, the medical director, for his criticism and advice.

COST OF AMBULANCE SERVICES

THE cost of running ambulance services under the National Health Service in the year ended March 31, 1951, is shown in a return [1] published last week.

Over the whole of England and Wales the average cost per vehicle mile was 1*s*. 8*d*., covering direct, agency, and supplementary services but not rail; and the cost per 1000 population was £169. The ambulance services of local authorities and their agents comprised, at the end of the twelve months, 4149 ambulances and cars and 10,986 operational staff. In addition, a large number of private cars were providing voluntary reinforcements through the hospital car service, and a number of patients travelled by rail under arrangements made by local health authorities. During the year the ambulance services ran more than 89 million miles and carried more than 9 million patients, compared with 79 million miles and 7 million patients in 1949.

The total cost of the ambulance services in the year was £7,411,502, of which £5,849,995 was the cost of directly provided services and £781,425 that of agency services. Other services, such as the hospital car service, cost £762,865, and rail journeys £17,217. An analysis of the expenditure on the directly provided services shows that of the total cost 59·7% represented operational staff, 19·5% fuelling and maintenance of vehicles, 5·6% provision of vehicles, 2·9% maintenance of buildings, furniture, &c., 1·2% provision of land and buildings, and 11·1% other expenditure, including administrative expenses.

PROTECTION OF THE WORKER

THE International Labour Conference, representing the governments, employers, and workers of some sixty countries, decided at its meeting in Geneva last month to pave the way for the possible adoption next year of international regulations to protect the health of workers in places of employment. The decision entails chiefly measures for combating occupational diseases, by early notification to labour or factory inspectors and by various preventive methods. Among other things, it was suggested that medical examination of workers employed in occupations involving special risks to

---

1. National Health Service: Ambulance Services Costing Return 1950–51. H.M. Stationery Office. Pp. 47. 4*s*.

health—either examinations carried out before or shortly after entry into employment, or periodical examinations, or both—should have a place in the proposed international regulations, but it should be left to national laws to define the classes of workers to be medically examined.

Meanwhile, the conference substituted a revised Maternity Protection Convention for that which it adopted in 1919. The new convention is substantially on the lines of the old, in that it maintains the right of working women to twelve weeks' leave before and after childbirth, to the receipt of cash and medical benefits during that period, and to immunity from dismissal from employment while on maternity leave. The main changes from the 1919 convention are: (1) the inclusion of agricultural and domestic workers; (2) the requirement that the cash benefit shall be not less than two-thirds of the woman's previous earnings; and (3) the relaxing of the previous stipulation that six weeks of the leave should be taken before confinement and six weeks after. The antenatal leave may now be as short or as long as necessary, provided that at least six weeks' postnatal leave is allowed.

The convention is supplemented by a recommendation proposing that the total leave period should be fourteen weeks, and containing a number of suggestions relating to facilities for nursing mothers and infants and to the protection of employed women during the maternity period against overstrain or work that might be harmful to their health or that of their children. The recommendation also amplifies the provisions of the convention concerning benefits. It proposes that these should include wherever practicable: general-practitioner and specialist outpatient and inpatient care, including domiciliary visiting; dental care; care given by qualified midwives and other maternity services at home or in hospital; nursing care at home or in hospitals or other medical institutions; and maintenance in hospitals or other medical institutions.

The British Government delegates did not vote either for or against the convention, taking the view that in this country the protection it embodies is already well provided under arrangements based partly on law and partly on practice, and that there would be serious disadvantages in substituting rigid legislation on the lines of the convention for the present elastic but adequate system of protection.

ESTIMATES FOR GENERAL PRACTITIONERS' REMUNERATION

THE Supplementary Estimates include an additional £35,456,000 for the remuneration of general practitioners under the terms of the Danckwerts award; and in a memorandum[1] the Government says that this total is compounded as follows:

Year	*£000*
1948–49 (arrears)	4275
1949–50 (arrears)	4805
1950–51 (arrears)	9359
1951–52 (arrears)	9963
1952–53	10,743
Gross total	39,145
Less estimated saving* on estimates for 1952–53.. ..	457
Less appropriations in aid (employers' and employees' superannuation contributions)	3232
Net total	35,456

*Provision made in current year's estimates for certain payments from the Inducement Fund which will not now be made.

The central pool has been calculated on the basis of a betterment factor of 85% in the years 1948–50, and of 100% in the years 1951–53; and allowance has been made for practice expenses by applying to gross remuneration a percentage of 36·5% in the years 1948–50, and of 38·7% in the years 1951–53.

The memorandum also includes the following table showing estimates, in the light of the figures accepted by Mr. Justice Danckwerts, of the total gross receipts of general practitioners in the National Health Service (estimates of net receipts in parentheses):

Year	1948–49 (from July 5, 1948)	1949–50	1950–51	1951–52	1952–53
Number of doctors*	18,812	18,969	19,227	19,565	19,850 (estimated)
	£000	*£000*	*£000*	*£000*	*£000*
Central Pool	30,396	41,268	41,533	41,433	53,482
Other receipts under Part IV of the National Health Service Act, 1946, and the National Health Service (Scotland) Act, 1947	2317	4920	5158	5384	
Receipts under Part II of the Acts	1009	1364	1100	1100	
Receipts under Part III of the Acts	268	362	400	400	
Receipts from other Government Departments	487	659	700	800	
Receipts from private practice	1479	2000	2000	2000	
Exchequer superannuation contributions ..	1609	2224	2357	2365	
Total amount under pre-award arrangements. (Net income, after deduction of practice expenses, in parentheses)	37,565 (24,441)	52,797 (34,338)	53,248 (33,553)	53,482 (33,700)	53,482 (33,700)
Additional amount due under award.. ..	4275	4805	9359	9963	10,743
Grand Total† (Net income, after deduction of practice expenses, in parentheses)	41,840 (28,716)	57,602 (39,143)	62,607 (42,912)	63,445 (43,663)	64,225 (44,443)

*Does not include 850 to 1000 doctors providing only limited services.
†Includes £120,000 to £200,000 for doctors providing only limited services.

Part IV receipts include: training of assistants, maternity medical service, ophthalmic medical practitioner fees, dispensing fees, inducement payments, and mileage (part).
Part II receipts include: part-time posts in hospitals, and payments to general practitioners in cottage or general-practitioner hospitals.
Part III receipts include: sessions at local-authority clinics, midwife aid calls, and vaccination and immunisation payments.
Receipts from other Government Departments cover fees for serving on medical boards.

A.C.T.H. AND CORTISONE IN RHEUMATIC FEVER

LAST year the American Heart Association and the Medical Research Council began a joint investigation into the relative value of A.C.T.H., cortisone, and aspirin in the treatment of rheumatic fever; 13 centres in the U.S.A., Canada, and Great Britain are participating. Prof. A. Bradford Hill and Dr. E. G. L. Bywaters represented the British centres at a meeting in Chicago last month of a panel of investigators engaged on this work. Dr. David D. Rutstein (Boston), moderator of the panel, later summarised the preliminary findings in the following statement:

> "A group of investigators in the United Kingdom, Canada, and the United States initiated in January, 1951, a coöperative study on the relative value of A.C.T.H., cortisone, and salicylates in the treatment of rheumatic fever and the prevention of rheumatic heart-disease. The

---

[1] Memorandum on the Supplementary Estimates for the additional sums to be provided for the remuneration of general medical practitioners in the National Health Service. Cmd. 8599. H.M. Stationery Office. Pp. 6. 4d.

plan of study provides for uniform criteria for the diagnosis of rheumatic fever and for the degree of rheumatic activity required for the admission to the study, the random allocation of patients to the three treatment groups, a defined dosage schedule of the drugs for a fixed period of time, a specified period of observation following treatment, and a long-term follow-up schedule. It also lays down precisely the frequency and type of clinical and laboratory observations to be carried out on each patient.

"To date, in all three countries, 658 cases have been admitted to the study and the analysis of rather less than half of these is the basis of the preliminary report. These cases were analysed for changes in those symptoms, signs, and laboratory observations usually considered important in evaluating the course of acute rheumatic fever. In the type of cases admitted to the trial and with the régime of treatment laid down, it appears that individual symptoms, signs, or laboratory observations may have been affected more favourably by one or another of these three drugs, but no consistent pattern is evident. In short, no firm conclusions can at present be drawn concerning the drug most effective in the control of the acute illness. The cases have not been under observation sufficiently long to provide data on the prevention of rheumatic heart-disease.

"Admission of new cases to the study will be brought to an end later this year. It is anticipated that a total of 750 cases will be available in all three countries for complete and detailed analysis of the effects of the drugs on the acute course of the disease and later, after adequate follow up, on the prevention of rheumatic heart-disease."

Parliament

Charges in the Health Service

IN the House of Commons on July 2, a general debate took place on the new regulations under the National Health Service Acts imposing or increasing charges for dental treatment, drugs and appliances, pay-bed accommodation in hospital, and hospital drugs and appliances.

Mr. HECTOR MCNEIL thought that the practitioner, to save his patient from being charged, would sometimes put more than one item on the prescription form and prescribe quantities larger than previously. Thus there might be no appreciable net saving. He was told that some outpatient departments were already not very zealous about the collection of the shillings. If such departments were concerned solely with their legitimate task of diagnosing, prescribing, advising, and dispensing, there would not be any time for this nonsense. Mr. ARTHUR BLENKINSOP said it was a tragedy that so many professional men today, particularly dispensing doctors, were obliged to spend so much more time on administrative tasks. Through these regulations they were being made into tax-gatherers.

Mr. H. N. LINSTEAD was surprised that this quite substantial administrative provision had been brought in with so much smoothness. Speaking as one who had daily contact with pharmacists, he believed that the new arrangements would soon settle down into a normal part of the health service.

Mr. JOHN BAIRD spoke of ill-feeling between the patient and the practitioner caused by the charges. According to the Minister's estimates the prescription charges were to bring in £13,000,000 while the dental charges might bring in only £7,000,000. But Mr. Baird forecast that less would be received from the prescription charges and more from the dental charges. Because of the dental charges people were not receiving treatment, and there was a great deterioration in the dental health of the nation.

Mr. IAIN MACLEOD, Minister of Health, said that from information received about the first month's working of the scheme five general conclusions had been reached about the hospital charges for drugs and appliances: (1) there had been no noticeable decline in the number of prescriptions dispensed; (2) there had been no variation in the quantities of drugs in prescriptions or in repeat prescriptions; (3) there had been no falling off in the number of outpatients; (4) there had been no noticeable increase in queueing in outpatient departments; and (5) generally no difficulties had been caused by the introduction of charges. There had been an extremely substantial fall in the estimates for dental treatment; a substantial proportion had been for people who could claim exemption. As there were not enough resources or dentists to meet all requirements, it followed that those most in need were getting treatment. The number of dentists in the school dental service had increased in the past six months from 716 to 793 and the trend was continuing. This meant that the priority classes would be better looked after than ever. In general practice during the first month—admittedly a month of fine weather with many people on holiday—there had been a 15% drop in prescriptions. Replies from ten regions showed that there had been no substantial change in the quantities of drugs prescribed on each prescription.

Mr. HILARY MARQUAND said that the Minister should not persuade himself that all was going well. The charges were felt severely in working-class areas, and the number of complaints would increase with the onset of winter.

The motion to annul the regulations relating to charges for drugs and appliances in England and Wales was negatived by 254 votes to 235.

QUESTION TIME

Limitations of the Danckwerts Award

Replying to Mr. J. S-W. ARBUTHNOT, Mr. R. A. BUTLER, Chancellor of the Exchequer, said that he wished to make it clear that the terms of reference of Mr. Justice Danckwerts's award were confined to the remuneration of general practitioners in the National Health Service and his award had no wider application. In accepting the results of the adjudication, which was of an exceptional nature, the Government had by no means adopted the view that similar adjustments in other fields should follow. In their view there was no justification for any assumption that the appropriate standard of remuneration for the professional classes was a rate of 100% above that in force in 1939. They considered that remuneration should be determined in the light of all relevant circumstances.

Industrial Reablement Units

Mr. HECTOR HUGHES asked the Minister of Labour if he was aware that the existing provision for the industrial rehabilitation and training of injured and handicapped persons was insufficient; that this was unjust to those persons and an economic loss to the community; and if he would set up a committee or commission to inquire into the subject.—Sir WALTER MONCKTON replied: There are now fourteen industrial rehabilitation units administered by my Department, including the residential centre at Egham. Over 30,000 people have attended them and 1373 are at present undergoing courses. As to training, the Government training centres are all open to disabled persons, and half of the courses are provided wholly or mainly for them. More than half those in training are disabled, and waiting-lists are now very short.

Dispensing Doctors and Prescription Charge

Replying to Dr. A. D. D. BROUGHTON, Mr. MACLEOD said that at the request of the British Medical Association it had been arranged that in the case of dispensing doctors, at the option of the patient, the prescription charge might be paid by postage stamp. The practitioner would convert any other payments to stamps and surrender them monthly to the executive council. The value of the stamps would be transferred from Post Office funds to Ministry of Health vote.

Crimes of Violence

In answer to a question Sir DAVID MAXWELL FYFFE, the Home Secretary, said that the numbers of persons found guilty in England and Wales of robbery, rape, and such offences of violence against the person as murder, attempted murder, manslaughter, wounding, and indictable assaults were 2717 in 1947 and 4274 in 1951.

Home Help Service

In answer to a question Mr. MACLEOD said that during 1951 166,759 people were assisted by the Home Help Service. He did not think that local health authorities required any special financial inducement to develop this service to the maximum extent practicable.

In England Now

A Running Commentary by Peripatetic Correspondents

GOING back to school after 30 years of general practice is an astonishing, stimulating, and humiliating experience. To many good G.P.s who have "kept up with the journals" it would be, no doubt, merely a matter of refreshing the memory; but to those of us who have lost touch with the hospital outlook a refresher course is something quite different. It is true that we can take up the story of, say, acute rheumatism or chronic nephritis and follow, with reasonable understanding, what has been happening in the meantime: but when it comes to electrocardiography, radiology, and biochemistry we are apt to find ourselves floundering in a strange, new world. Even the medical jargon of our youth has changed almost beyond recognition, and there has been an intense proliferation of syndromes. Morale is a little restored in the post-mortem room, but perhaps more so at the bedside, where, despite an abysmal ignorance of academic medicine, we have at least learnt by experience that common things are common. Here we contrive to keep our ends up with our bright young classmates and even to some extent with our brilliant and polite young tutors. Here also we sometimes make the right diagnosis, albeit for quite the wrong reasons, not scientifically but by employing that more or less inspired guesswork which we learnt from our pastors and masters in the 1920s—and nowadays this simply will not do.

* * *

"What's Australia like?" we asked our new orthopædic resident. He looked up from his macaroni cheese: his eye fell on the semolina pudding waiting on the hotplate. "A lot of protein," he said wistfully.

Only a few days later I came across him on the balcony dilating on the hard lot of our feathered friends to a couple of soft-hearted female patients. "A long winter," he said, "A late spring." Tears filled their eyes; they promised regular donations of crusts and crumbs to the absurdly plump birds that flock round their beds at mealtimes.

I wish he'd never let me share his guilty secret. How can I face the good ladies, or the old men on the balcony below, also pledged to sacrifice the last morsels of their every meal? Replete with roast pigeon, tortured by remorse, I follow him from bed to bed, urging them to keep up the good work: and I find it as much as I can do not to glance up to the roof to see if the traps we set each night are keeping up the good work too. "The trouble with you English," declares my resourceful Australian colleague, "is that you don't exploit your natural resources. There's a lot of protein here, too."

* * *

In the recently published work of Rhine of Duke University on parapsychological phenomena there is a notable omission which has not escaped the attention of Continental workers in the same field. Bumpf (*Med. Z. Kotentleer.*) describes the phenomenon of the psychological induction of electric currents by apparently unrelated and non-psychological stimuli. He takes as the field for his observations the house telephone, and his first note is that the best results are achieved within narrow time-limits—in this series of observations between 8.30 and 9 in the morning. Greips, in a short but brilliant essay entitled Hindernisse beim Durchfall (*Klin. Wschr. Stuhlsitzens*) comes to almost identical conclusions.

Put simply, the gist of the observations made by these and other workers is that the induced currents in the telephone circuit are *directly proportional* to the intensity of the psychosomatic stimulus. Thus if on the one hand the psychical urge (*Drang*) of the Stimulus Supplying Subject (S.S.S.) is feeble or lacking, results will be poor. And if, on the other hand, the somatic desiderata—which form a group including posture, clothing, &c.—are not complied with, success need not be looked for. The standard of success as accepted by all workers is the induction of a current of such strength as to result in prolonged ringing of the bell. A notable observation is that a feigned *Drang* and simulated physical dispositions of posture, clothing, &c., such as are liable to occur in laboratory experiments, inevitably fail. This leads to the conclusion that all work must as it were be in vivo, and not in vitro.

Some observers lay stress on the posture of the S.S.S., who they insist must be seated. No induction takes place while the standing position is maintained. For the disposition of the clothing which he describes as necessary, Bumpf has coined the rather clumsy term *Hosenuntergang*, which perhaps unnecessarily complicates the terminology, since the quite satisfactory description of the French workers *culotte en bas* could scarcely be bettered. Be that as it may, to Bumpf is due the credit for the primary observation that under the above conditions current induction invariably follows of such strength that the telephone bell rings continuously, ceasing only when the S.S.S. disrupts the conditions—i.e., changes the sitting posture for another, and alters the clothing disposition.

Two further observations also lie to his credit. The first is that current induction is stronger, and bell-ringing louder, if at the same time there is an *added auditory stimulus*, which he this time appropriately names *Wassersplusch und Papiergeräusch*. The second is that the approach of the S.S.S. to the bell breaks the circuit and the bell stops ringing, starting again however as soon as the other conditions—distance, posture, clothing, &c.—are reimposed.

These observations are challenged by several French workers who have been unable to get parallel results, and maintain that the German observations are vitiated by a factor which they term *blague*. The Germans retort that the French failure to obtain results is simply due to the fact that the necessary stimuli, especially *Wassersplusch und Papiergeräusch*, are rarely to be found in France.

Research continues and new discoveries are claimed from many quarters, but up to the present there is no doubt that Bumpf has written the most.

Unrecorded Minute from Dublin

Mover of Motion: I ask the chairman's advice. May I divide this motion into two parts?

Chairman (looking at clock): I think the two parts could reasonably be taken as a reference to council.

M. of M. (dourly): I did not ask that. May I move it in two parts?

C. (cautiously now): Well, I think it would be best taken as a whole.

M. of M. (triumphantly): If you had said that it could be divided, I would have asked permission to withdraw the first part.

C. (quickly to meeting): Is permission given to withdraw the first part.

M. of M. (even more quickly): But I have not asked permission because you would not let me divide it.

C. (desperately and dimly through the laughter): Do you ask permission to withdraw the first part?

M. of M.: I cannot because I have not been allowed to divide it.

C. (seeing the end in sight): Do you ask permission to divide the motion?

M. of M. (quietly): No.

Motion hastily carried unanimously in toto.

* * *

Agricultural scientists in Ohio have discovered that poultry and pigs gain weight more rapidly on feeding-stuffs enlivened with a small amount of a detergent akin to those soapless soaps that precipitate a latent exophthalmos in the housewives on our hoardings. The mode of action of the detergent, when given by mouth, is not clear: it may inhibit the growth of harmful bacteria in the gut, or, by ensuring a thorough "wetting" of the food by the digestive juices, it may promote absorption. The amount used is apparently not enough to whip the food-trough into a lather; nor does it make the animals foam at the mouth; so this discovery seems to have nothing to do with Inner Cleanliness.

Letters to the Editor

SPORT AND MEDICINE

SIR,—A British Association of Medicine and Sport has recently been formed. Its aims are to promote the study and investigation of the medical and scientific aspects of sport in all its branches. Membership will be open to medical representatives nominated by all national sporting bodies and to any interested medical men and women with a qualification registrable in the United Kingdom. It is hoped that this association will attract a large membership of doctors. Those who are interested are invited to write for particulars to the Hon. Secretary, British Association of Medicine and Sport, c/o British Olympic Association, 71, St. George's Square, London, S.W.1.

ADOLPHE ABRAHAMS
President.
ARTHUR PORRITT
Chairman.

TREATMENT OF URÆMIA IN CHOLERA

SIR,—It is well known that anuria and azotæmia are constant accompaniments of the cholera syndrome. Next only to circulatory failure, uræmia is the most important fatal complication of cholera. In the series described by Rogers,[1] uræmia was responsible for death in 3·5% of all cases (20% of all deaths), even after he had instituted the standard treatment by transfusion of alkalis.

In Lahiri's[2] series the proportion of deaths from uræmia varied from 22·7 to 50% of the fatalities, according to whether sulpha drugs had been withheld or used in treatment; these drugs definitely aggravated kidney failure in his series.

The causes of uræmia in cholera are partly prerenal and partly renal. The underlying causative factors of prerenal uræmia are shock and the great loss of chlorides, the former resulting in the pronounced diminution of blood-flow and filtration pressure through the kidney. The important thing to be noted is that, in cholera, the suppression of urine continues despite the restoration of the blood-volume and blood-pressure, and of the specific gravity of the blood by means of transfusions.

Besides these circulatory factors, the other underlying causes of this somewhat specific type of kidney failure peculiar to cholera must be sought in the changes in the structure and function of the nephron. Some of these changes have been described in detail, or are suggested as the causative factor, by Chatterjee.[3] Most of those changes are reversible; so if the patient survives the uræmia, he makes a complete recovery and never suffers from subsequent kidney failure or its sequelæ.

The structural changes in the nephron consist mainly in a peculiar swelling and "fibrillation" of the basement membrane of the malpighian corpuscle and of the tubular epithelium. There is also acute capillary dilatation of the medullary region.

This reversible acute kidney failure of cholera is non-inflammatory and non-degenerative. There is little evidence of any toxic degeneration of the tubules, or for the matter of that of any so-called "cholera toxin." The kidney lesions heal spontaneously, and chronic nephritis or nephrosis never ensues.

This extremely acute but completely reversible kidney failure led me in last year's cholera epidemic to use antihistamine drugs and ascorbic acid in those cases where restoration of the specific gravity of the blood was not followed by urination. By this means the proportion of deaths from uræmia in cholera was reduced to less than half the lowest figure of Rogers[1] and Lahiri.[2] A very large number of last year's patients were admitted more or less moribund, as a large proportion were refugees from Pakistan; yet uræmic deaths amounted to 9%, in contrast to the 20% reported by Rogers and the 22·7–50% described by Lahiri.

Encouraged by these results we have repeated and modified this treatment in the 1952 epidemic, and to our surprise there has not been a single uræmic death in our cholera cases this year, during which we have so far treated 740 cases. In every case of suppression of urine we give intravenous injections of ascorbic acid 500 mg. twice daily. This starts urination in 70% of cases. In those cases where urination is not initiated by this treatment we inject an anti-histamine compound ('Antistin' 0·1 g. in 2 ml.) intramuscularly in the kidney region. We have found that injection in this way is more efficacious than administration intravenously or by any other method. We are unable to explain this difference. It is rather a surprise to see the onset of urination in cases which we would formerly have regarded as hopeless.

The treatment of circulatory shock and collapse in cholera is purposely not considered here; nor are the great advances in our knowledge of the electrolytic changes in the plasma and body-fluids in shock due to various causes, including cholera.[4] The treatment of the kidney disorder is supplemental to the treatment of circulatory shock and collapse.

I would again repeat that the administration of ascorbic acid in rather large doses, along with an antihistamine compound in the more difficult cases, after restoration of blood-volume, has eliminated anuria and uræmia in cases admitted to our cholera ward in this year's epidemic.

Calcutta National Medical Institute,
Entally, Calcutta, India.

PERIODIC DISORDERS OF CHILDREN

SIR,—There is a great deal to delight the psychiatrist in Dr. Franklin's wise and admirable paper (June 28).

There is a tendency to diagnose a neurotic disturbance in the child by negative physical, rather than by positive psychiatric, findings. It is evident that far too much emphasis is placed on the presenting physical symptom. A careful psychiatric history will always reveal other positive symptoms of a psychiatric disturbance, often masked by the parents' over-concern with the alarming and often socially inconvenient presenting symptom. Furthermore, one cannot relate the severity of the psychiatric disturbance to that of the physical symptoms. Acute, dramatic, physical symptoms are often the most modifiable. A diagnosis of a psychiatric disturbance can be made at an early stage, but the mechanisms of the psychopathology will usually only be evident after an exhaustive examination of the parents, child, and environment. A neurotic child invariably denotes a neurotic parent.

Dr. Franklin makes it plain that bad social conditions result from faulty emotional attitudes and that the social conditions do not in themselves make for emotional problems in the child, as these are dependent on the same faulty emotional attitudes. But I do not agree that explanation is important in treatment. My experience is that explanation is futile, because the faulty parental emotional state does not allow of its acceptance. Furthermore, experience shows how disappointing is the response of the child's condition to mere instruction of the parents in the daily management of the child. The basic faulty emotional attitude, responsible for the bad management, remains untouched by a mechanical change of technique. The preoccupation with the presenting physical symptoms inevitably leads to the offering of symptomatic relief and the use of suggestion. No doubt it is this that leads Dr. Franklin to suggest magic and ritual as the best line of treatment. The clearing up of a symptom by suggestion merely leads to the substitution of another; and, if the new symptom is socially less undesirable, this carries the danger of the discontinuance of the parents' attendance and the ignoring of the underlying neurosis, both in the child and the parents. One should, correctly, ask why a parent's neurosis becomes canalised in the child and why the parent is neurotic at all. These problems are indivisible; for removing the child from the parent, whilst it may cure the child, invites the parent to exhibit the neurosis in another channel—perhaps in another child.

---

[1] Rogers, L. Bowel Diseases in the Tropics. London, 1921; p. 117.

[2] Lahiri, S. *Brit. med. J.* 1951, i, 500.

[3] Chatterjee, H. N. *Trans. R. Soc. trop. Med. Hyg.* 1941, 34, 337.

[4] Chatterjee, H. N. *Ibid*, p. 379; *Ibid*, 1946, 39, 321.

It matters little who takes the psychiatric history, or who assesses the psychiatric symptoms; but it is clear that the child psychiatrist, or, better, family psychiatrist, should explore the psychopathology and apply the psychotherapy. The greater part of his time will be spent with the parents.

"ISONIAZID"

SIR,—Anyone who in the last few months has had anything to do with the new drugs isonicotinic acid hydrazide and its derivatives would welcome a word which did not take quite so long to say or write. A portmanteau word such as isoniazid, used in the June number of the *American Review of Tuberculosis* and in your excellent article of June 28, is at first sight attractive. But if we attempt to cram a portmanteau too full it may burst; and when we coin new words we should see that, like portmanteaux, they perform the function for which they were designed and do not become nuisances instead. I suggest that the use of isoniazid (or isoniazide) as a *generic* name may be not only confusing but dangerous too. We know already of several other related substances of similar activity against tubercle bacilli, and no doubt we shall hear of many more. The ones already known differ widely in toxicity and in effective dose. If we are to use abbreviations we must know precisely which drug we are abbreviating, and we should be quite clear whether the word isoniazid (if that is to be the word) refers to isonicotinic acid hydrazide (isonicotinyl hydrazine, I.N.H., I.N.A.H.) itself or is intended to cover the whole group of related hydrazides.

HOSPITAL ADMINISTRATION

SIR,—It surprises me that Dr. Stephen Taylor (July 5) finds administration "often tedious, repetitive, and dull." It is hard work, often difficult, and sometimes exasperating; but tedium is the child of idleness, not of work. It is only superficially repetitive. Just as no two cases of pneumonia are exactly alike, no two administrative situations are exactly alike, and it is in the adjustment of action to unique cases that the art of administration resides. And any job that deals with people is never dull, but lively, varied, and fascinating as humanity itself. Such at least is my own experience.

It surprises me even more that he prefers lay to medical administrators. When I first undertook administration I was impressed by the number of medical decisions I had to take, and at the range of medical knowledge I needed to help me to make them wisely. The lay administrator can get medical advice if he asks for it, but he may not always recognise the medical nature of his problem. He may, for example, decide about flooring for wards without realising that he is influencing the problem of cross-infection. One cannot have too much medical knowledge if one is to administer a hospital. As for personal relations, if my colleagues think meanly of my clinical skill I can bear it cheerfully (always reserving my own opinion on that question) provided they realise that I am trying as hard as they are to do my best for the patients. In my experience the only doctors who resent medical knowledge in an administrator are those who like him to accept a view simply because they have pronounced it, and are unprepared to support it with reasons; but there are not many like that.

Giggleswick, Settle, Yorks.
D. P. LAMBERT.

CORTISONE IN ADRENAL VIRILISM

SIR,—The valuable preliminary communication of Dr. Bishop and his colleagues in your issue of June 28 is obviously of great interest. As the reported demonstration of the inhibition of pituitary-adrenocortical activity is limited to one patient, you may consider it worth while to add this brief record of another case of adrenogenital syndrome, commencing at puberty, under my care some months ago, in which there was a similar response to cortisone.

The patient was a female of 18 years who, at the age of 14, began to menstruate scantily and at long and irregular intervals, and developed hair on the face and acne on the face and back. She weighed 112 lb. and was 60 in. in height. On examination she had a narrow pelvis, small flat breasts with small nipples, and hair on the sides of the face, upper lip, and cheeks, on the buttocks, in the anal and vulval regions, and on the arms and legs. Her back was covered with severe and extensive acne. The clitoris was grossly enlarged. She had been treated with ethinyl œstradiol without obvious effect. The 24-hourly urinary values for 17-ketosteroids at intervals of about 3 days before the administration of cortisone were 35, 32, 22, 35 and 23 mg.; and corresponding values during the injection of 100 mg. of cortisone were 7·6, 5·4, 6·4, and 5·3 mg.—a clear-cut and persistent reduction.

The patient was unwilling to remain in hospital to permit the study of 17-ketosteroids after leaving off the cortisone. A return to pre-cortisone values after some weeks might be anticipated. There was no obvious effect on the hirsutism during the three weeks of administration, but the patient was delighted with the almost complete disappearance of the generalised acne, which had previously been refractory to all forms of therapy. The effects of longer-term therapy will await larger supplies of cortisone for such kind of work. Enlargement of the breasts, more regular menstruation, and some amelioration of the hirsutism would not be improbable.

The history and investigations are in keeping with adrenal hyperplasia and not neoplasm. There would seem little doubt that cortisone is effective in inhibiting pituitary-adrenocortical activity in some patients.

The hormone assays were carried out by Dr. E. Kawerau at St. Mary's Hospital and by Mrs. A. M. Robinson at St. Bartholomew's Hospital. The cortisone was allocated by the Medical Research Council.

S. LEONARD SIMPSON.

BRITISH STUDENT TUBERCULOSIS FOUNDATION

SIR,—This foundation was formed last year with the aim of opening in this country a 100-bedded rehabilitation centre, where students convalescing from tuberculosis can be fitted for return to college by courses of study including lectures, set reading and essay writing, and tutorials. In a little over eighteen months British students have collected some £20,000 towards this.

This April the North-West Metropolitan Regional Hospital Board agreed to open a small experimental unit for men at Pinewood Hospital in Berkshire.

This centre is expected to be ready in September; it has accommodation for 16 student patients in one self-contained ward. This is to be divided into three parts: a dining-room where all meals will be taken, a lounge, and a bed-ward where students can read in silence during rest periods. The medical care and supervision of the patients will be the responsibility of the physician superintending the hospital. The academic side will be the responsibility of the foundation. Those admitted will have to be recovering satisfactorily; they must be sputum-negative. As only a minimum of nursing staff will be available, students must be fit enough to do a few light duties for themselves, such as making their beds. They must be able to take all meals up and stay up and dressed for some four hours a day at least. Patients will be expected to abide by the rules of the sanatorium during their three or four months' stay there.

The foundation is to be responsible for occupational treatment and is now making arrangements for university teachers, principally from the University of London, to visit the centre regularly to give lectures and supervise individual courses of study.

Entry is open to all full-time male students from any part of Great Britain, whatever their race, colour, or creed. It is expected that applications will greatly exceed the number of places available, and it is to be understood that selection of medically suitable candidates rests finally with the regional hospital board; however, the board has agreed to accept the advice of the foundation as to academically suitable applicants as far as possible. The foundation will be pleased to receive, at the earliest opportunity, applications from any full-time student who would like to come to Pinewood and who expects to be fit to do so by the autumn, or at any time throughout the coming year. Applicants need consider themselves under no obligation to come if or when they are offered a place. It is important that application should be made early—any time up to six months ahead of the expected date of fitness—so that delays in admission and empty places can be avoided. The foundation will keep in touch with applicants to confirm their medical progress.

Such is our scheme. I would be grateful if any doctor in touch with, or in charge of, a tuberculous student who might wish to avail himself of these facilities, would either give the student the address of this foundation or communicate with us. Application forms and detailed information may be obtained from this office on request.

British Student Tuberculosis Foundation, 6, Gordon Square, London, W.C.1.

NICOLAS MALLESON
Hon. Secretary.

PROVISION FOR THE MENTALLY DEFECTIVE

SIR,—I am disturbed by certain statements in your annotation of June 14. There appears to be confusion between the terms "mental defective" and "educationally subnormal." In connection with mental defectives, for example, you mention that in Sheffield there are 360 places in day special schools, but in actual fact under the Education Act mentally defective children are not eligible for admission to school at all. The schools to which you refer are for children who are educationally subnormal, and the mention of them in an article on mental defectives is therefore incorrect. Incidentally, the number of places should read 395 not 360.

You will excuse me for feeling hot on this subject; but school doctors, who ascertain all children who need special educational treatment, are with some success endeavouring to dissipate the stigma formerly attached to schools for educationally subnormals. In doing so they quite rightly assure the parents that the schools have no connection with mental deficiency, and that the children are admitted purely on educational grounds. Children who are found by the doctor, on examination for admission to the special school, to be mentally defective are, of course, reported to the local health authority as ineducable in a school sense, though they may profit by the practical type of education given at an occupation centre.

Furthermore, the mention in your article of the three special classes for dull children in Sheffield is, if I may say so, even more out of place. These classes are remedial in nature; and once the child is fulfilling his potentialities—that is his attainments matching his mental age—he passes into the ordinary school stream. The intelligence of these children, therefore, may be of any grade within the normal, though, in the main, it is the lower normal who need such help. The classes are under the direct supervision of the child-guidance centre. Sheffield has many other classes for dull children which are of a different nature.

It is disappointing to parents to find that a child of theirs is of the educationally subnormal standard, and they need from the school medical officer assistance in facing the fact and realising the importance of accepting a place offered in a special school. The removal of the stigma is therefore of supreme importance to them. It is also of equal importance to the child, who is already aware that he is less clever than his contemporaries and should not have to refute the unfair suggestion that he is also mentally defective.

Sheffield.

M. C. TAYLOR
School Medical Officer.

BUTAZOLIDINE

SIR,—In six months I have used 'Butazolidine' in the treatment of some fifty patients. Of these, some old, some young, 37 were suffering from rheumatoid arthritis in an active phase, 6 from osteo-arthritis, 2 from spondylitis, the rest from gout, Paget's disease, "periarthritis" of the shoulder, "sciatica" and non-articular rheumatism following a "chill." They were given 1 g. of butazolidine as a 5 ml. intramuscular injection daily for eight days, then on alternate days, and later every third day, usually for a period of four weeks, sometimes longer.

The relief of pain and stiffness that followed was almost constant and in some instances dramatic. Apart from the improvement of function with increase in range of joint movement there was no constant objective change. The blood picture remained unaltered. Complications have not been serious. The drug was stopped in 2 patients because of a complaint of nausea and sleepiness (unaccompanied by alteration in the white blood-cell count). In 1 there was a sudden onset of auricular fibrillation; after administration of gr. 6 of digitalis the rhythm reverted to normal. In another there was an abscess at the site of injection in the buttock.

This drug is not "curative," but I believe that it can play a useful rôle in clinical practice. Already I have found it of value as the first step in the management of a patient with active rheumatoid arthritis who is put on the waiting-list for admission to hospital, or who is starting a course of gold, or is about to have physical treatment, manipulation, or the application of plasters. If given in conjunction with cortisone, by relieving the pain due to permanent joint changes it may enable us to cut down the dose of cortisone necessary to "control the activity" of the disease.

Some twenty years ago, while on a visit with my then chief, the late Dr. Matthew Ray, to Aachen, Professor Krebs showed us the value of amidopyrine in the treatment of spondylitis. On our return we used it with success but gave it up because of the repeated warnings of the complications that might follow. Last week Professor Lucherini, the eminent Roman rheumatologist, while going round my wards told us that he gave his rheumatic patients 3 g. of amidopyrine daily with great success. In thousands of cases he had noted no complications. He urged me to adopt his method. This I am not ready to do, but I am using butazolidine (Geigy) and strongly recommend other people to try it.

London, W.1.

FRANCIS BACH.

OSLER MEMORIAL TABLET

SIR,—After attending the summer meeting in Oxford, on June 28, of the pædiatric section of the Royal Society of Medicine, held at the Radcliffe Infirmary, with cases and demonstrations in the Osler lecture-theatre and tea in the garden of Osler House, one naturally visited the Oslers' old home, "The Open Arms," at 13, Norham Gardens, to pay tribute to the memory of one of the greatest clinicians of all time, whose genuine love for children has been so graphically described in Harvey Cushing's *The Life of Sir William Osler* and Edith Gittings Reid's *The Great Physician*.

Sir, imagine one's surprise to find, pinned to the front door, a notice: "The Bureau of Statistics has moved to other premises." The spacious and once beautiful house was empty and in disrepair, and the huge garden a wilderness, overrun with weeds.

It may not be generally known that this house received its name from the unbounded hospitality that the late Sir William and Lady Osler, during their years in Oxford, showered on literally hundreds of medical men and their wives from Canada, the United States of America, Great Britain, and Europe, as well as undergraduates at Oxford. Sir William lived there from 1905 till his death on Dec. 29, 1919, while occupying the chair of regius professor of medicine at the university. Lady Osler continued to live in the house until her death on Aug. 31, 1928.

It makes one sad to think that this once famous house bears no tablet commemorating the fact that this outstanding personality—"The Shakespeare of Medicine"—once lived there and, in his will, bequeathed it to his own beloved college, Christ Church, as a suggested home for future regius professors of medicine at Oxford.

May I, Sir, suggest that a fund be opened at once to erect such a tablet, the balance of the proceeds from which to go towards some worthy cause such as the committee responsible for its distribution might think fit?

The council of the Osler Club of London, jointly with the council of the Osler Society of Oxford, would seem to me to be the appropriate body to put this suggestion into effect; and I appeal to the profession in Great Britain, the United States of America, and Canada to give it their wholehearted support.

This seems to me a singularly opportune moment to bring this matter to the attention of our profession, as on Saturday, July 12, the Osler Club of London is holding its annual dinner to celebrate the 103rd anniversary of Osler's birth.

42, Corringway,
London, W.5.

L. CARLYLE LYON
Assistant Hon. Secretary,
Osler Club of London.

COMPLICATIONS OF CONTROLLED HYPOTENSION

SIR,—Your leading article last week contains a very reasonable call for caution against the indiscriminate use of methonium compounds for the control of bleeding in surgery, but some of the evidence put forward is irrelevant.

The decrease in the renal blood-flow which follows the administration of pentamethonium iodide (C5) in *conscious* subjects[1] is, of course, no indication of what may occur under general anæsthesia. In fact, we have shown that under cyclopropane and ether anæsthesia the renal blood-flow is unaffected by C5 despite a marked drop in the systolic pressure to 50–80 mm. Hg for periods of up to half an hour.[2] Whatever the dangers of this technique—and they are very real—there is no evidence that it impairs the renal circulation.

BENEMID IN THE TREATMENT OF STREPTOCOCCAL ENDOCARDITIS

SIR,—Last week's article by Dr. Baker and Dr. Pilkington on this subject is of great importance in drawing attention to the existence of a drug which by its power of restricting tubular secretion of penicillin can be life-saving. I have recently treated successfully one case of staphylococcal septicæmia with 'Benemid' and penicillin after heroic doses of the latter had failed, and after failure with full doses of aureomycin and the other more recent antibiotics. Similarly, complete success attributable to the combination of benemid and penicillin has been seen in two cases of infective endocarditis due to *Streptococcus viridans* of unusual resistance.

It should be emphasised that tubular "blockage" is useless unless the therapeutic agent with which it is employed is known to be excreted largely or in part through the tubular epithelium. Self-evident as this may seem, I have observed on more than one occasion that it is not so.

London, W.1.

PREVENTION OF SEASICKNESS

SIR,—The investigation by Dr. Glaser and Dr. Hervey[1] into the prevention of seasickness with hyoscine, 'Benadryl,' and 'Phenergan,' was well planned from a statistical point of view, but their article contains fallacies that should be corrected.

Discussing dimenhydrinate ('Dramamine'), they infer that the 8-chlorotheophyllinate portion of its molecule is unnecessary to its action against motion sickness, and suggest that diphenhydramine (benadryl) without this portion of the molecule might control motion sickness. Therefore, they dismiss dimenhydrinate without further comment.

It is not known what influence 8-chlorotheophylline exerts to control motion sickness, but the drug is *not* inert. Although it has been shown to have no effect on the vomiting produced by apomorphine, the conclusion that it cannot have any effect on motion sickness is fallacious.

Haley and Harris[2] demonstrated that the action of dimenhydrinate was contrary to that of diphenhydramine and many other anti-histamine agents. They concluded that dimenhydrinate caused *dilatation* of the arterioles of the frog's mesentery; the other anti-histamines tested (including diphenhydramine) caused *constriction* of capillaries.

The more recent work of De Jongh et al.[3] is of great importance; their experiments show that 8-chlorotheophylline has the same effect on the frog's isolated heart and on the circulation in the perfused isolated hindquarters of the rat and frog as has theophylline—another proof that 8-chlorotheophylline is not inert. Further, they show that 8-chlorotheophylline enhances the narcotic action of sodium pentobarbitone in mice. The dual action cited above makes it improbable that the presence of 8-chlorotheophylline in the molecule of dimenhydrinate has no bearing on the action of the drug, even though its exact function remains undetermined.

The investigations of Gutner et al.[4] establish additional evidence that the 8-chlorotheophylline portion of dimenhydrinate gives rise to pharmacological action different from that of diphenhydramine.

Glaser and Hervey state that Chinn et al.[5] have given doses of hyoscine amounting to 2·25 mg. daily with no side-effects other than dryness of the mouth in most subjects and blurred vision in some. But they omit Chinn's comment that, because of the "high incidence of side effects" in a number of subjects, the drug could not be administered continuously over several days. Gay and Carliner[6] in their original study of dimenhydrinate gave many soldiers 300–400 mg. daily for as long as 11 days with no side-effects except drowsiness in an occasional subject. In a much larger number of subjects than either Chinn et al. or Gay and Carliner studied, Wright[7] found that by the end of 2 hours the army motion sickness preventive (M.S.P.) "cured" 50% of the sick patients, whereas diphenhydramine and dimenhydrinate "cured" 88% and 98% respectively.

Lastly, Glaser and Hervey prescribed the maximum dose of hyoscine (1 mg.) to the subjects of their experiment, but they prescribed 25 mg. of diphenhydramine and 25 mg. of promethazine hydrochloride (phenergan). In their trials Gay and Carliner, Chinn et al., and Wright

prescribed 50–100 mg. as often as every 4–6 hours. The efficacy of the drugs prescribed by Glaser and Hervey, therefore, cannot be evaluated on an equal or a comparable therapeutic basis. There *is no doubt that* the dose of diphenhydramine was too small. Further, the drug was given too long before the start of their experiment. Rough sea was encountered $1^1/_2$–2 hours after intake of the drug and the soldiers were exposed to seasickness for 2 *additional* hours. Therefore diphenhydramine was expected to be effective for 4 hours. The experimental reports of Landau and Gay [8] and Landau et al.[9] had long since established that diphenhydramine is one of the short-acting anti-histamine drugs in contrast to promethazine hydrochloride.

In conclusion the single-dose trials of Glaser and Hervey are quite inadequate to prove which of the anti-seasickness drugs are comparably effective. Further, their failure to make use of reported experimental facts diminishes the usefulness of their studies and militates against the validity of their conclusions. I trust that in their next trials they will use dimenhydrinate, diphenhydramine, promethazine hydrochloride, and hyoscine in comparable and adequate dosage in a *much* larger number of subjects; and I suggest that they should not be satisfied with a sea trip of less than 8 days, on which they are present as actual observers.

In your issue of March 8 Dr. Glaser and Dr. Hervey describe a motion sickness in which the volunteers were subjected to artificially induced turbulent water. I do not believe that the motion of a ship on the high sea during the winter months can be reproduced in this way.

LESLIE N. GAY.

*** We have shown Dr. Gay's letter to Professor Glaser and Dr. Hervey, whose replies follow.—ED. L.

SIR,—Please permit me to reply to Dr. Gay's complaints about publications by Dr. Hervey and myself.

Dr. Gay states that it is not known what influence 8-chlorotheophylline exerts on motion sickness. This is incorrect. In fact, Dr. Hervey and I have quoted the evidence which suggests that 8-chlorotheophylline exerts no influence on motion sickness. Dr. Gay's references to other actions of 8-chlorotheophylline and of certain histamine antagonists are irrelevant to the problem of motion sickness.

Dr. Gay criticises us for quoting Chinn et al.'s [10] findings rather than their comments. I respect Dr. Chinn's opinions, but I think he would be the first to agree that observations mean more than comments. Chinn and his colleagues did record auditory hallucinations in 1 of 88 men who were given 3·25 mg. of hyoscine in 36 hours; but a single case does not prove anything.

I do not know why Dr. Gay quotes observations about M.S.P. This preparation contains a trifling amount of hyoscine, and Dr. Hervey and I were not concerned with it.

Dr. Gay blames us for giving comparatively small doses of one drug. He may be right, but we based our dosage on the available data and gave the reasons for our choice.

Dr. Gay states that we gave the maximum dose of hyoscine. This is incorrect. Holling et al.[11] gave 20% more hyoscine than we did, and Chinn et al. gave larger total quantities.

Dr. Gay states that the effects of one of the drugs *may* have worn off before some of our tests were completed. This may be true; but any drug which ceased to have effect after less than 4 hours was useless under the conditions with which we were concerned, and we did not claim or imply that our results were valid beyond those conditions.

Dr. Gay believes that the motion of a ship on the high seas cannot be reproduced by artificial waves and he is free to do so, but Dr. Hervey and I accepted the advice of an Admiralty expert on wave motion who took painstaking records and whose data were given in our publications.

Since we quoted 27 references in one paper it seems odd that we should be blamed for failing to make use of reported experimental facts, but it is true that we did not include some of Dr. Gay's own claims. Rather than say more, I will refer to opinions held by distinguished American scientists [12–14] and one of your contemporaries.[15]

Department of Physiology,
University of Malaya, Singapore.
E. M. GLASER.

SIR,—I should like to endorse Dr. Glaser's reply to Dr. Gay.

The 25 mg. of benadryl given by us was not such a very small dose. It contained as much diphenhydramine as 46 mg. of dramamine; and we have referred to two reports showing no statistically significant difference between the effectiveness of benadryl and dramamine, given in doses in the ratio of 1 : 2, in preventing motion sickness. We did give phenergan, which appeared to be more effective, in a larger dose during the later series of experiments, with little difference in the results.

It is, of course, only claimed that our results were valid for the conditions under which they were obtained, and "a sea trip of not less than eight days" would obviously have been better in some ways. None the less, protection for a short time is sometimes required in practice (e.g., in assault craft). Our experiments were designed to investigate protection for short periods, to give statistically valid results and to avoid any possible effects of bias on the part of the observers or subjects.

Medicine and the Law

A Question of Fees

A REPORT by its ophthalmic services committee that was approved by the London Executive Council when it met on June 26 draws attention to a course which, without specifically violating the terms of service, is regarded as "clearly an undesirable and unworthy practice."

The patients' version of the facts appears to have been accepted. Mrs. A had her sight tested under Supplementary Ophthalmic Services arrangements by Mr. X, an ophthalmic medical practitioner on the London Ophthalmic List. Forms O.S.C. 1 and 2 were completed and no charge was made. Mrs. A was accompanied by Mrs. B (her mother), who asked to have her own sight tested. Mr. X fixed an appointment for this purpose and later Mrs. A arranged with him by telephone that on the same occasion he would also test Miss C (her aunt). When Mrs. B and Miss C attended at his consulting-room, he asked them for "a small fee of £1 1s. each." This surprised them because they supposed they were being treated (like Mrs. A) under the National Health Service; but they paid the fee and were, they said, assured by Mr. X that they would obtain their glasses free under the scheme on his prescription. He advised them to go to a named firm of dispensing opticians, and he telephoned details to the firm. When they visited the firm to get their glasses, they were told that they could not have them until the duly

authorised forms O.S.C.2 were handed over. Mrs. A thereupon reported the matter to the committee.

Mr. X told the committee that he had regarded the ladies as private patients. He said he had been advised by a legal organisation specialising in medical matters that there was nothing to prevent his seeing a patient privately one day and their returning to him another day to obtain a copy of the prescription on O.S.C.2. The organisation denied having so advised. The committee pointed out that such a course would result in the practitioner receiving two fees for the one service—viz., a fee from the patient for the "private" consultation and, after the prescription had been copied on to form O.S.C.2, a sight-test fee under National Health Service arrangements. The committee conceded that a practitioner practising under the National Health Service is not thereby debarred from accepting private patients. As no National Health Service form was initiated by Mr. X for Mrs. B and Miss C, the committee could not definitely decide that he had accepted them as N.H.S. patients. The committee, however, were satisfied of his awareness that the two patients wished their sight to be tested under the N.H.S. and of his having deliberately diverted them into "private" channels. It was this practice which, as already stated, the committee stigmatised as undesirable and unworthy. If persisted in, it might furnish grounds for representations to the tribunal that the continued inclusion of Mr. X in the Ophthalmic List would be prejudicial to the interests of the service. In view of his statements the committee found themselves inclined to conclude that he sought to induce the patients to come back to him for a further consultation for which a sight-testing fee could be claimed from public funds.

In formulating their recommendations the committee announced that they found no failure by Mr. X to comply with the Terms of Service. They thought, nevertheless, that he should be warned that persistence might lead to the removal of his name from the Ophthalmic List, and they recommended that the special attention of the Minister of Health be directed to the acts disclosed in the case.

Employee's Duty to Disclose Disability

The Court of Appeal has modified the award of damages to the widow in the case of Cork *v.* Kirby Maclean Ltd.,[1] where the husband who suffered from epilepsy had a fatal fall from the platform on which he was working. His employers had been at fault inasmuch as the platform was not of the width and was not equipped with the guard-rails required by the Building (Safety, Health and Welfare) Regulations. The defendant employers contended that the deceased had been subject to epileptic fits for 10 years and had been under treatment for epilepsy only 10 days before his death; his doctor had warned him that he must not work above ground level and he had promised to obey; he had not, they said, disclosed these facts to them. Mr. Justice Donovan held that the fatality must be deemed due to the employers' breach of their statutory duty unless they proved the contrary. He was following, it seems, a dictum of Lord Justice Scott in Vyner *v.* Waldenberg Bros. (1945)—a case of injury by a circular saw where the protective guards required by the Woodworking Machinery Regulations had not been provided.

Lord Justice Singleton[2] expressed the view that Lord Justice Scott's opinion went too far. Mr. Cork's fatal injury had two causes. One was the employers' breach of the regulations; the other was the workman's failure (a breach of his duty towards his employers and his fellow-workmen) to disclose his disability. Both sides were at fault, and the Court of Appeal was unable to decide that one party was more negligent than the other. Applying the Law Reform (Contributory Negligence) Act of 1945, it ruled that each side was responsible for half the damage. Accordingly Mr. Justice Donovan's award to the widow is reduced by one-half.

Obituary

PERCIVAL HORTON-SMITH-HARTLEY

Kt., C.V.O., M.A., M.D. Camb., F.R.C.P.

Sir Percival Horton-Smith-Hartley, consulting physican to St. Bartholomew's Hospital, who died on June 30 at the age of 84, came of a family eminent in the legal profession. Perhaps it was the influence of this inheritance that made him unique among the physicians of his time.

The eldest son of Mr. R. H. Horton-Smith, K.C., he was educated at Marlborough and St. John's College, Cambridge. After taking a double first in the natural sciences tripos he continued his medical studies at St. Bartholomew's Hospital, where he qualified in 1893. After holding house-appointments at Barts and a fellowship at St. John's College, he spent some years of postgraduate study in Paris and Vienna. Soon after his return to London he joined the staff of the Metropolitan and Brompton Hospitals. In 1899 he was elected F.R.C.P., and the following year he delivered the Goulstonian lectures on typhoid. In 1906 he became assistant physician to Barts.

He was appointed C.V.O. in 1912 and created a knight bachelor in 1921. For many years he was a member of the court of the Company of Ironmongers and in 1942 he was elected master.

[Vandyk

"Despite an orthodox medical education," writes F. R. F., "Sir Percival was an individualist and he differed in many ways from his contemporaries, for his interests and abilities led him along original paths in his professional as well as his private life. His wide culture enabled him to enjoy his life to the full, and the many fields into which his trained intelligence attracted him were a constant surprise to his acquaintances. His kindliness, his sympathy, and his interest in human beings had a therapeutic value for his patients, perhaps of even greater importance than his knowledge of scientific medicine, and the example he gave by his care for his patients was of greater educational value than his formal instruction. He would have made a wonderful family doctor, but his erudition and his mental abilities marked him out for a career in academic surroundings where his educational value had a wider scope. The scientific age and the rapid advances in medical science that occurred during his time had little influence on his professional life and he remained essentially a humanitarian scholar and a wise physician. As the wife of a colleague once said 'Sir Percival is a dear.'

"To the younger generation he is best known as the author with Sir Richard Douglas Powell of the later editions of the textbook on *Diseases of the Lungs and Pleuræ*, and the versatility of his interests is seen in the book which he wrote with Mr. H. R. Aldridge of the British Museum on *Johannes de Mirfield of St. Bartholomew's, Smithfield* and his article in the *British Medical Journal* (1939) on the Longevity of Oarsmen. He would surprise his friends by offering them seats at Lord's for a test match. In preparing his lectures he took great pains, and his fluency and correct use of words were a delight and a lasting example. He will be greatly missed by his students and colleagues, and his gentle influence on their way of life, their ideals, and their sense of values will never die."

Sir Percival married in 1895 Miss Josephine Hartley, of Hartley, Kent, and in 1904 he assumed the additional surname of Hartley. She survives him with a daughter and a son who is a master at Eton College.

Notes and News

SECURITY MEASURES AT BROADMOOR

THE last escape from Broadmoor had such dreadful consequences that the Minister of Health appointed a committee to inquire into the security arrangements. The members were Mr. J. Scott Henderson, Q.C. (chairman), Dr. P. K. McCowan, Captain C. Waterhouse, M.P., and Mr. K. G. Younger, M.P. They have reported promptly, and all their recommendations have been accepted in principle by the Government.

Broadmoor receives those ordered to be kept in safe custody during Her Majesty's pleasure (which includes people found insane on arraignment for a criminal offence, or criminals found guilty but insane), those whom the Home Secretary may order to be removed to a mental hospital, and those prisoners certified before or after trial to be insane. Formerly it was managed by a council of supervision appointed by the Home Secretary, but under the Criminal Justice Act, 1948, it was transferred to the Minister of Health and put under the management of the Board of Control. The nursing staff have Civil Servant status and are members of the Prison Officers' Association, though they are regarded as part of the National Health Service.

On June 1 this year there were 891 patients in Broadmoor—701 men and 190 women. The medical staff consisted of the medical superintendent and his deputy, and two other doctors. The post of a fifth medical officer is at present vacant.

The patients live in a series of blocks, each with three wards, and are allotted to different blocks according to their mental condition and behaviour. The block for refractory patients consists of single rooms, while other blocks have dormitories; and in the wards for the best patients single rooms may be awarded as a privilege. The most dependable patients are allowed to go into the terrace gardens and canteen, or visit other blocks to see friends among the patients.

In 1932–40 there were no escapes from Broadmoor; but since 1950 there have been 6, of which the last was in April of this year. The full staff of attendants authorised is 279, but on June 1 there were only 260—193 men and 67 women. Moreover, though the pensionable age is fifty-five, 14 of the male staff were over sixty, and 5 of these were over sixty-five. The wage now payable to a male nurse recruit is £5 4*s.* a week; and though this amounts to £40 a year more than the wage paid to students in ordinary mental hospitals (who in turn receive £30 a year more than students in general hospitals), it does not compare as favourably with the wages of other—and possibly more congenial—local employments as did the wage of 1938. Hence young entrants to the staff are few, and the average age of the male staff has risen, since 1938, from forty to forty-five, and of the female staff from thirty-one to forty. The committee recommend that sufficient increases in pay should be made to attract suitable applicants for training; and that the pay and conditions of service of the nursing staff should not be automatically linked with those of the National Health Service.

The escapes in recent years have been due, the committee find, to carelessness on the part of the staff; and this in turn has been due to lack of adequate numbers of staff of the right quality. Some added difficulties in maintaining supervision have arisen because of building work in progress, and some of the workmen employed by the Ministry of Works maintenance staff have pass keys to move about inside the institution, though only the resident engineer and foreman of the works have keys to get in and out. The committee suggest that much of the traffic by maintenance personnel inside the institution could be reduced by putting the works yard outside the security wall; and they point out that as few keys as possible should be in the hands of workmen. In 2 cases patients have escaped by making keys, and modern locks are now being fitted throughout the building.

Patients wear ordinary clothing except when at work, when their clothing is distinctive. The committee propose that in blocks where it seems desirable the patients' ordinary clothes should be in a locked cupboard, and no patient should have access to them without the knowledge of a nurse.

They insist that, in the event of an escape, the public are entitled to an effective warning. A distinctive siren or other audible alarm should be put into action by the officer on duty as soon as an escape is discovered; and this should be electrically coupled to an alarm at Wokingham police-station. They also suggest that the Chief Constable of Berkshire should consult the Post Office authorities about the best way o warning schools of any escape which takes place during school hours; and that he should work out, with the medica superintendent of Broadmoor, a plan of coöperation between the staff of the institution and the police. In proper cases the committee think, the British Broadcasting Corporation should be asked to give priority to an announcement of an escape.

POSSIBLE RISK FROM CHLORAMPHENICOL

IN the U.S.A. the Food and Drug Administration has initiated a nation-wide survey after receiving reports o many cases of aplastic anæmia following treatment with chloramphenicol. The *New York Times* (July 5) says that doctors are being warned to make precautionary blood studies when administering this drug. It has been emphasised, however, that there is still no definite proof that chloramphenico is unsafe, since in many of the cases sulphonamide compounds and other antibiotics had been administered.

HOSPITAL PATIENTS AND INSURANCE BENEFITS

THE National Insurance Advisory Committee have recommended [1] that when insurance benefits are increased [2] patients who have been in hospital for a year should keep more of their benefit. The committee reaffirm the principle that there should not be double provision under the public social services for the same need. Since a patient while in hospital receives free maintenance in addition to treatment, his National Insurance benefit, which also includes provisions for maintenance, is therefore reduced. The committee recommends that the reduction for hospital maintenance should be increased broadly in proportion to the increases in benefit. The following regulations have been drawn up to implement the committee's recommendations:

After 8 Weeks in Hospital

The reduction after eight weeks for patients without dependants (now 10*s.*) will be increased to 12*s.* 6*d.* weekly. The reduction after eight weeks for patients with dependants (now 5*s.*) will be increased to 6*s.* 6*d.* weekly. Together with the increased rates of benefit these increases mean that single people on sickness benefit will receive during the rest of their first year in hospital about 4*s.* more than now, and the married patient about 10*s.* 6*d.* more. Single retirement pensioners who received the full 4*s.* increase last year will receive the same amount as now and married pensioners 2*s.* 6*d.* more.

After 12 Months in Hospital

The pocket-money allowed to long-term patients, with or without dependants, after they have been in hospital for a year (now 5*s.*) will be increased to 6*s.* 6*d.* weekly. The pocket-money allowed to patients suffering from respiratory tuberculosis, after they have been in hospital a year (now 10*s.*), will be increased to 11*s.* 6*d.* weekly.

Resettlement Benefit

In future the usual weekly instalment by which resettlement benefit is paid out (now £2) will be increased to £2 10*s.*

The committee will consider any objections to these regulations which are sent before Aug. 5 to the secretary, National Insurance Advisory Committee, 30, Euston Square, London, N.W.1.

ADVENTURES IN TWO WORLDS

Dr. A. J. Cronin has had an eventful life and his telling of it [3] makes an engaging if at times irritating book; engaging for its flow of anecdotes, irritating for its too-vivid medical drama. For instance, the story of the girl dying in a lonely house on a Welsh hillside because her father obstinately refused to call a doctor is a good one, but it is marred by the "not a second to lose" Hollywood version of the mastoid operation that saved her. But, as Dr. Cronin could justifiably retort, he is not writing for medical readers, whose delicate sensibilities are certainly not those of the reading public in general. *Hatter's Castle*, consigned in manuscript to the dustbin by the disconsolate author, has since gone through 29 impressions, and *Adventures in Two Worlds* may well do the same. A sister whom he came to know in a convent, herself a raconteuse specialising in tales of 15th-century Italy, had, he says, "a vivid imagination which, I assure you, did not diminish the interest of her stories." Nor does Dr. Cronin's verve detract from his story as a story, but it introduces colours too glaring to fall pleasingly on the eye of another doctor.

University of Oxford

In a congregation on June 26 the degree of D.M. was conferred on the following:

R. H. Cowdell, H. J. F. Cairns (in absence).

The university has accepted from the Nuffield Foundation a grant of £2500 a year for two years towards the cost of research on the synthesis of cortisone.

University of London

Dr. A. W. Woodruff has been appointed to the Wellcome chair of clinical tropical medicine tenable at the London School of Hygiene and Tropical Medicine.

Dr. Woodruff graduated M.B. at the University of Durham in 1939. After holding resident appointments at the Royal Victoria Infirmary, Newcastle upon Tyne, he joined the medical branch of the Royal Air Force in 1940, serving later as a medical specialist. In 1941 he took his M.D., in 1944 the M.R.C.P., and in 1946 the D.T.M.&H. The same year he was demobilised from the R.A.F., and later he worked in the department of medicine at Ibadan Medical College, being also attached to the London School of Hygiene and Tropical Medicine. At present he holds the appointments of senior lecturer in clinical tropical medicine at the school and of first assistant at the Hospital for Tropical Diseases. Last year he was awarded the Katherine Bishop Harman prize. He has published papers on anæmia of pregnancy among Africans in Nigeria, on tropical sprue, and on the absorption of folic acid.

Mr. F. L. Warren, D.SC., reader in biochemistry at University College, has been appointed to the chair of biochemistry at London Hospital Medical College.

Dr. Eric Neil, senior lecturer in physiology at Middlesex Hospital Medical School, has been appointed to the readership in physiology at the school.

University of Manchester

The following have been successful in recent examinations:

M.D.—J. L. Braithwaite (commendation), P. R. Duncan (commendation), E. G. Wade (commendation), Roger Warwick (gold medal), J. L. Wilkinson (commendation), R. M. Winston.

M.B., Ch.B.—I. S. Bailey (honours), W. M. C. Allen, S. B. de C. Baker, J. G. Bancroft, Margaret E. Bennett, Barbara M. Benson, A. D. Bostock, Carl Burns, L. J. Chadwick, Don Clynes, J. R. Coope, A. B. Cooper, D. R. Dodsley, H. J. Done, Bernard Dudley, F. B. Eyres, Joyce A. Fiddick, P. V. Fitton, J. D. Fletcher, Peter Griffiths, Linton Grimshaw, J. A. M. Henderson, R. F. Heys, Joyce Hougie, Edmund Howarth, Helena E. Hughes, Mary I. J. Hughes, G. C. Jackson, J. B. Jacovelli, C. H. St. J. James, H. B. Kedward, J. H. Kemp, I. M. Kendal, B. W. Laithwaite, A. B. Lishman, Jean M. Lumb, Dorothy J. Marsden, C. N. Matthews, Peter Mawdsley, Douglas Millington, R. G. Mitchell, Marjorie Naylor, Joyce Newman, J. T. Newton, D. P. Oakley, T. E. Ormerod, J. F. Patrick, J. R. Raby, Derek Robinson, Audrey Ross, J. G. Searle, J. J. Shepherd, Geoffrey Taylor, G. W. Taylor, Sheila A. S. Thompson, Leslie Turner, E. G. O'H. Warburton, Robert Welton, Roger Whitaker, John White, J. A. Wright, Joan P. Wright.

University of St. Andrews

At recent examinations the following were successful:

M.D.—D. G. Adamson and J. M. Johnstone (with commendation).

Final Examination for M.B., Ch.B.—W. N. Laing, I. R. McLellan, J. H. Margerison, A. J. Mutch, G. M. Ross, R. B. Skeoch, G. C. Winch (with commendation); J. T. Allardice, John Anderson, Bryan Ashworth, C. E. Ballance, D. A. Barbour, Ralph Bibby, J. M. C. Bisset, Jack Boswell, Elizabeth H. Brown, J. R. W. Bryce, Ronald Cable, E. A. Cameron, A. A. Campbell, James Carnegie, Elizabeth F. H. Clarke, Helen P. Cochrane, F. C. Crowe, W. S. Cunningham, W. J. Dally, Joan C. Davey, J. D. Denison, Anne C. Donald, F. H. Doyle, Audrey V. E. Duthie, J. M. Eaton-Turner, D. R. Edmiston, T. R. Elder, Flora M. L. Emery, J. S. Garrow, J. L. Graham, R. W. Henderson, G. W. Johnston, Clarence King, Anne G. Lacey, I. G. D. Laing, J. M. Langlands, D. M. Lindsay, R. W. D. Low, Rosaleen Lynch, Lena M. MacBean, H. W. McFarlane, J. B. MacGillivray, Norman McLeod, J. R. Marshall, Helen Menzies, Grizel M. B. Patrick, P. J. Pearce, N. T. Piercy, Fay M. Rennie, Robert Robertson, H. H. Robinson, H. S. Ross, Marion M. T. Roy, James Sinclair, R. F. Stark, W. B. Steel, Michael Steele, Marjory Stewart, M. K. Thompson, William Turner, G. M. J. White, D. L. Whitton, R. W. Wright.

University of Aberdeen

On July 4 the honorary degree of LL.D. was conferred on Colonel H. E. Shortt, F.R.S., professor of medical protozoology in the University of London and head of the department of parasitology in the London School of Hygiene, and on Mr. D. Landsborough Thomson, PH.D., professor of biochemistry in McGill University, Montreal.

On July 3 the following degrees were conferred:

M.D.—Robert Semple (with commendation); Bessie C. Laing, Jean M. Sheach.

Ph.D.—P. G. Walker.

M.B., Ch.B.—I. H. Anderson, A. D. Calder, George Cassie, A. G. Chisholm, T. J. Crowley, A. R. Dow, Alison H. Edwards, Peter Harvey, A. H. Innes, N. D. Innes, T. I. Kemp, J. H. Lewis, K. L. Lipp, G. B. McCutcheon, A. M. Macleod, Archibald Morrison, David Ruddiman, A. R. L. Russell, R. A. W. C. Smith, W. J. M. Stewart, D. J. W. Sutherland, I. R. Swanson, J. G. Weir.

University of Dublin

On July 3 the following degrees were conferred:

M.D.—G. L. Daly, P. G. Daly, D. F. Doherty, J. R. Hassard, T. B. Madden, J. S. Ruddell, S. B. Sachs.

M.Ch.—W. G. Fegan.

M.B., B.Ch., B.A.O.—E. T. Baldwin, Colette A. Barouch, E. G. Bennet, Mary E. Bewley, G. J. Bigley, R. C. P. Bradley, Fodla B. K. Burnell, G. A. H. Cookson, Lois R. Davidson, R. J. Draper, I. A. Eppel, Noreen M. H. Evans, S. S. Faloon, B. W. Fisher, Peter Froggatt, J. H. van R. Hofmeyr, James Hunter, Eunice Hurworth, H. Q. Hutchings, R. F. Hutchings, Janet B. Hyde, W. T. Irwin, H. R. B. Jack, Christopher Kennedy, Gordon King, H. G. Knox, B. F. St. L. Liddy, G. S. McCarthy, Elisabeth M. McNab, R. W. Mitchell, Oluyinka Olumide, Freda M. E. Parker, Barbara W. M. Partridge, W. J. C. Pearson, A. F. C. Scott, J. A. Scully, R. B. S. Smith, A. A. Sugerman, T. E. W. Winckworth, Mary V. Young.

Royal College of Surgeons of England

On July 3 Sir Clement Price Thomas, Mr. C. Naunton Morgan, and Mr. Hedley Atkins were elected members of the council. The result of the poll was as follows:

	Votes
SIR CLEMENT PRICE THOMAS (Westminster Hospital)	826
C. NAUNTON MORGAN (St. Bartholomew's Hospital)	770
H. J. B. ATKINS (Guy's Hospital)	727
R. Milnes Walker (Royal Infirmary, Bristol)	588
Ian Aird (Postgraduate Medical School of London)	576
V. W. Dix (London Hospital)	479
H. C. Edwards (King's College Hospital)	471
R. H. O. B. Robinson (St. Thomas's Hospital)	416
M. F. Nicholls (St. George's Hospital)	247
H. W. S. Wright (Queen Mary's Hospital for the East End) ..	242

In all 1988 fellows voted; and in addition 25 votes were found to be invalid.

British Association of Urological Surgeons

The eighth annual meeting of this association was held in London from June 26 to 29 under the presidency of Mr. E. W. Riches. The following were elected officers for 1952–53:

President, Mr. E. W. Riches; vice-president, Mr. T. J. Millin; hon. secretary, Mr. A. W. Badenoch; hon. treasurer, Mr. R. H. O. B. Robinson; hon. editorial secretary, Mr. J. D. Fergusson; council, Mr. J. C. Anderson, Mr. David Band, Mr. J. G. Yates Bell, Mr. T. L. Chapman, Prof. V. W. Dix, Mr. W. H. Graham, Mr. J. G. Sandrey, Mr. H. Hamilton Stewart.

American Research Grants

The American Embassy and the United States Educational Commission in the United Kingdom offer grants to assist senior British scholars to lecture or carry out research in the universities of the United States during 1953–54.

The minimum period of grant assistance for which application will be accepted will be three months; the maximum will be ten months. The monthly stipend will not be more than $270. No living allowances will be provided for the dependants of grantees. Candidates who receive these grants will be expected to attend American universities as visiting scholars, and, therefore, no provision will be made for the payment of tuition fees. To attend an American university as a visiting scholar, applicants should be able to show considerable professional or academic attainment. Candidates may receive a grant to cover expenses of travel to and from the United Kingdom and the university which is their destination in the United States.

Application forms may be obtained from the Assistant Cultural Relations Officer, Room 302, 41, Grosvenor Square, London, W.1, after Aug. 1.

International Congress of Internal Medicine

The second congress of the International Society of Internal Medicine will be held in London from Sept. 15 to 18. Mr. Iain Macleod, the Minister of Health, will attend the opening by Sir Russell Brain, P.R.C.P., on Monday, the 15th, at 11 A.M. The scientific programme is to consist solely of symposia, and the subjects have been chosen from a wide field in the hope that as many members as possible will join in the discussions.

The opening speakers and subjects are as follows:

Dr. C. D. de Langen (Utrecht), Dr. A. L. Froehlich (Antwerp), Prof. A. C. Frazer (Birmingham), and Dr. Chester M. Jones (Boston), Sprue Syndrome—Idiopathic steatorrhœa and Cœliac Disease; Prof. J. G. G. Borst (Amsterdam), Dr. F. T. G. Prunty (London), Prof. R. Platt (Manchester), Dr. R. S. Mach (Geneva), Prof. R. A. McCance, F.R.S., Miss E. M. Widdowson, D.SC. (Cambridge), Prof. J. Hamburger (Paris), Dr. O. J. Broch (Oslo), and Mr. A. W. Wilkinson (Edinburgh), the Clinical Importance of Disturbances of Fluid and Electrolyte Balance; Dr. J. R. Paul (Yale), Dr. Herdis von Magnus (Copenhagen), and Dr. W. Ritchie Russell (Oxford), Neurotropic Virus Disease; Sir Alexander Fleming, F.R.S. (London), Dr. F. Magrassi (Naples), Prof. A. Kekwick (London), and Prof. C. Jimenez Diaz (Madrid), Antibiotics in Man.

A limited number of non-members may attend the congress on payment of a fee; only members of the International Society may take part in the discussions. Further particulars may be had from the secretary of the congress, Sir Harold Boldero, Royal College of Physicians, Pall Mall East, London, S.W.1.

Mass Radiography in the Birmingham Region

The mass-radiography service in the Birmingham region has been augmented by the formation of two new units. The Stoke unit (Dr. E. Posner) will serve the Potteries and the north of the region, whilst the *Birmingham mobile unit* (Dr. W. M. Dixon) will operate in and around Birmingham.

Faculty of Radiologists

The following officers were elected at the annual general meeting on June 20: president, Dr. Peter Kerley; vice-*presidents, Prof. A. S. Johnstone and* Mr. C. J. L. Thurgar; hon. treasurer, Dr. J. W. McLaren; hon. secretary, Dr. Rohan Williams; hon. editor, Miss Margaret Tod.

Hospital Dental Service

The Minister of Health (R.H.B.[52]75) has suggested that a grade of whole-time general dental surgeon should be introduced in hospitals. The day-to-day work of this officer would include the conservation of teeth by means of routine fillings, scaling *and treatment of the gums, the extraction of teeth* for the removal of oral sepsis or the relief of pain, and the supply of dentures. He might serve two or more hospitals *within a group. The grade would, in the Minister's view,* be of particular value in long-stay hospitals where general dental work is often undertaken for inpatients. There may also be *scope for general dental surgeons in other hospitals, but it is* not intended at this stage to offer short-stay patients dental treatment beyond what is needed as part of their medical care or for relief of pain. The Minister hopes that the introduction of this grade will attract to the hospital service those who wish to make a career there without aspiring to senior staff status; in particular he thinks that some dental registrars who do not obtain senior registrar appointments may welcome the opportunity which it affords. The salary scale for the new grade is to be £900 × £30 to £960 × £40 to £1200 × £50 to £1500.

The Minister of Pensions has appointed Prof. Walter Mercer chairman of the Standing Advisory Committee on Artificial Limbs in succession to Mr. St. John Dudley Buxton.

Sir Harold Gillies has been appointed emeritus consultant plastic surgeon at Rooksdown House, Basingstoke, on his retirement from active work at this hospital.

In an advertisement by Boots Pure Drug Co. Ltd., which appeared in our advertisement columns last week the quotation from the *Archives of Dermatology and* [illegible] *“... therapeutic results confi* [illegible] *in placing undecylenic acid—* [illegible] *studied.”*

Diary of the Week

JULY 13 TO 19

Monday, 14th

GUY'S HOSPITAL MEDICAL SCHOOL, London Bridge, S.E.1
5 P.M. Prof. H. Sicher (Chicago): Functional Anatomy of the Temporomandibular Articulation.
INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5 P.M. Prof. Lorimer Dods (Sydney): Some Aspects of Pædiatric Endocrinology.

Tuesday, 15th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Mrs. Margaret Hill: Dangers of Chronic Inactivity in Old Age. (F. E. Williams lecture.)

Wednesday, 16th

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1
5.30 P.M. Prof. Urpo Siirala (Turku, Finland): Frequency of Ear Diseases and the Prevention of Deafness.

Thursday, 17th

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE
7.30 P.M. (26, Portland Place, W.1) Brigadier J. S. K. Boyd, F.R.S., Dr. G. H. Hitchings, Mr. I. M. Rollo, and Dr. L. G. Goodwin: Symposium on the New Anti-malaria Drug—Daraprim.

Friday, 18th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. V. Zachary Cope: Sir John Tomes—A Great Dental Pioneer. (Charles Tomes lecture.)

Appointments

CLARK, J. S., M.B. Durh.: M.O., Nyasaland, in the Colonial Medic Service.
GOULD, L. N., M.R.C.S., D.P.H.: M.O.H. for the Haltemprice U.D. and divisional M.O. for the East Riding of Yorkshire.
KENNY, SHEILA, M.D. Dubl., D.M.R.D.: consultant radiologis South Down and South Armagh hospital group, Norther Ireland.
LECKIE, F. H., M.C., L.R.C.P.E., M.R.C.O.G.: asst. obstetrician an gynæcologist, East District Hospital and Glasgow Roy Infirmary.
O'HANLON, R. H., M.R.C.P.I., M.R.C.O.G.: honorary asst. gynæcologist, Dr. Steeven's Hospital, Dublin.
O'TOOLE, P. M., M.B. N.U.I., D.A.: anæsthetist, Dublin Corporatio
ROBERTSON, DANIEL, M.B. Glasg.: appointed factory docto Lincoln district.
SIMM, FRANCIS, M.R.C.S.: asst. M.O.H., Warrington, Lancashire.
STEVENSON, D. K., M.B. St. And., M.R.C.P.: consultant che physician, Bradford.
STRACHAN, A. B., M.B. Aberd.: appointed factory doctor, Goo district, Yorkshire.
TAYLOR, ROBERT, M.B. Edin., D.P.H.: deputy M.O.H. and depu school M.O., Middlesbrough.
WILLCOX, D. R. C., M.B. Lond.: S.H.M.O. in clinical patholog Bethlem Royal Hospital and Maudsley Hospital, London.

Manchester Regional Hospital Board:

BEETLES, E. A., M.S. Madras, D.M.R.D.: asst. radiologist, Macclefield and South Cheshire Hospitals and Parkside Hospita Macclesfield.
HADELMAYR, ILSE, M.D. Vienna, D.A.: asst. anæsthetist, Oldha hospitals.
POLLOCK, MARGERY, M.B. Dubl., D.A.: asst. anæsthetist, We Manchester hospitals.

North-East Metropolitan Regional Hospital Board:

BATES, MICHAEL, F.R.C.S.: *maximum part-time* regional thorac surgeon (consultant).
[illegible] M.R.C.S., D.A.: full-time or maximu [illegible] (consultant), Oldchurch Hospital.
LUNN, G. M., M.B. Camb., F.R.C.S.: part-time surgeon (consultant), Metropolitan Hospital.
MONRO, J. W., M.B. Camb., D.A.: part-time anæsthetist (consultant), Whipps Cross Hospital.
PHILIPP, E. E., F.R.C.S., M.R.C.O.G.: maximum part-tim obstetrician and gynæcologist (consultant), Oldchur Hospital.
SAVAGE, C. S., F.R.C.S.: part-time E.N.T. surgeon (consultant Rush Green Hospital.
STRIDE, S. D. K., M.R.C.S., D.A.: part-time anæsthetist (consultant), Broomfield Hospital.

Sheffield Regional Hospital Board:

BAUER, JACOB, M.D. Warsaw: *director, Lincolnshire* mas radiography unit.
FORBES, D. E. P., M.D. Edin.: deputy physician-superintenden Leicester Isolation Hospital, and Chest Unit, Groby Roa Leicester.
TEWFIK, G. I., M.D. Lond., D.P.M.: asst. psychiatrist, Middlewoo Hospital, Sheffield.

Welsh Regional Hospital Board:

BECKETT, H. DALE, M.R.C.S.: asst. psychiatrist (S.H.M.O. Morgannwg H.M.C.
DAVIES, WILLIAM, M.R.C.S., D.C.H.: asst. pædiatrician (S.H.M.O. East Glamorgan area.
HUGHES, ANEURIN, M.B. Lond., M.R.C.P.E.: consultant physicia North Monmouthshire, Newport, and East Monmouthshi H.M.C. groups.

The Terms and Conditions of Servic[illegible] *Dental Staff apply to all N.H.S. hospit*[illegible] *otherwise stated. Canvassing disqualifies,* [illegible] *visit the hospital by appointment.*

Births, Marriages, and Deaths

BIRTHS

CAMPBELL.—On June 25, at St. Brenda's Nursing Home, Clifto to Mary (née Clarke), wife of Dr. A. M. G. Campbell—a daught (Fiona Mary).
NAISH.—On June 21, at Bristol, to Nora, wife of Dr. John Nais —a son.
TANNER.—On June 21, to Mary, wife of Mr. Clive H. Tanner, F.R.C.S., of 61, Walter Road, Swansea, Glam—a daughter.

MARRIAGES

PIRRIE—HAMILTON.—On July 1, at Glasgow, Robert Pirrie, M.B., to May Hamilton, S.R.N.
REY—WOOD.—On June 21, in London, C. Humphrey J. Rey, M.R.C.S., to Thelma M. Wood.

DEATHS

DAVID.—On July 5, at Fyfield, Essex, Archibald Sinclair David, M.R.C.S., D.P.H.
HARE.—On July 2, at Birkdale, Lancs, Alfred William Hare, M.B. Aberd.
HARTLEY.—On June 30, 1952, in London, Sir Percival Horton-Smith-Hartley, KT., C.V.O., M.D. Camb., F.R.C.P., of Adkins, Ingatestone, Essex, aged 84.
MACLEOD.—On July 3, at St. Thomas's Hospital, London, Henrietta Mary Macleod, M.R.C.S.
RAYMOND.—On July 2, in Colchester Hospital, George Raymond, M.R.C.S.

FEEDING DISORDERS IN INFANTS
THEIR INTERPRETATION

C. WILFRED VINING
M.D. Lond., F.R.C.P., D.P.H.
VISITING PÆDIATRICIAN TO THE DEWSBURY HOSPITALS;
EMERITUS PROFESSOR OF CHILDREN'S DISEASES IN THE UNIVERSITY OF LEEDS

THE term "feeding disorders" is now in general use as a description of the group of symptoms, common in the early weeks and months of life, which includes vomiting, posseting, screaming, "colic," "wind," abnormal stools, and failure to gain weight satisfactorily. Formerly these symptoms were ascribed to "infantile dyspepsia," which seems to imply an inability to digest food or some part of the food, or that the food itself is proving harmful to the child; and there is still, I think, a considerable body of opinion that supports this idea. But the truth, I believe, is that these symptoms are chiefly due to hunger, the result of underfeeding. The feeds may be too small or too dilute, or, because of wrong feeding technique, the infant may be unable to obtain enough.

It will be appreciated that I bear in mind that vomiting and/or loose stools may be associated with congenital obstruction of the œsophagus, pylorus, duodenum, or beyond; or with some bacterial infection, especially gastro-enteritis. Gastro-enteritis and "infantile dyspepsia" are very often confused; and, because the treatment of the one is the exact opposite of the treatment of the other, care must be taken in diagnosis. Gastro-enteritis starts suddenly, and the quick change in the frequency and appearance of the stools is distinctive. Listlessness, refusal of food, and some degree of toxæmia are usual.

THE PAST FIFTY YEARS

Half a century ago, when I was a medical student at St. Mary's Hospital, the infant-mortality rate of the Borough of Paddington was 155, and I well remember the large number of marasmic babies which were brought to the medical casualty department and the clinics of that hospital. Gastro-enteritis was then prevalent, and I bring to mind the queues of mothers with extremely ill babies in their arms. Voluntary welfare centres came into being, frequent discussions took place at medical societies, and infant feeding and infantile dyspepsia became major problems. The press were asking why medical students were not taught about infant ailments, and why these matters were not referred to at the final examinations. The reason no doubt was that consultants and the medical profession generally knew little about them. Dr. Ralph Vincent put forward his system of "percentage feeding," and Dr. Truby King produced handbooks offering fantastic formulæ for artificial infant feeding. The dangers of overfeeding were emphasised by all, and fat dyspepsia, curd and protein dyspepsia, sugar dyspepsia, and even salt dyspepsia were described and added to the increasing worries of medical students.

The vomiting of curds, or their passage in the stools, was considered sufficient evidence that the fault lay in the protein content of the milk, but we students sometimes wondered what else a baby was expected to vomit when fed with milk! Nor was it explained to us that most stool curds were not protein curds at all. For some years so-called curd dyspepsia held the field as the main cause of the infant feeding disorders. Citration and prolonged boiling of milk were recommended to overcome this difficulty, but the commonest recommendation was modification of cow's milk ("humanisation") by dilution with water and the addition of cream and sugar. Very soon this supposedly ideal artificial method of infant feeding deteriorated into feeding the baby with overdiluted milk, and sugar. I once possessed a treasured poster, issued some forty years ago by a medical officer of health of one of the largest cities in the north, which advised mothers, if they could not breast-feed their babies, to use a half-and-half mixture of milk and water. And we still wondered why marasmus was so common among infants.

Marasmic infants succumb readily to infection, and their proportion of the infant population at that time was undoubtedly a grave potential danger and an important cause of the high mortality-rate. Dirty feeding-appliances were blamed and the importance of germ infection emphasised, but there were many who believed that "infantile dyspepsia" was due to the milk itself.

Why is the marasmic infant now rarely seen? Certainly no one factor can be claimed to have wrought the change; but the marketing of dried milk, first introduced about thirty years ago, almost certainly did more than anything else to reduce infant mortality. Some ascribed this improvement to the absence of bacteria in the dried-milk feed; but, looking back, it seems to me more likely that the real reason was that for the first time the artificially fed baby was presented with a square meal and a square deal. When a measureful of milk powder is added to an ounce of water, the baby is given the equivalent of whole cow's milk.

The baby, however, continued to experience disappointments. Some makers of dried milk did not supply a metal measure, and teaspoons were recommended; but, because milk powder is very light in weight, a flat large teaspoonful of powder added to an ounce of water provided the baby with only the equivalent of approximately a half-and-half milk and water mixture. Even when metal measures for milk powder were available, the baby was still denied a well-concentrated feed, because mothers were (and still are) told to measure the water with tablespoons, and this means an overdiluted mixture because most tablespoons measure a good deal more than half an ounce. Unfortunately, few at that time realised that good nutrition is Nature's chief protection against infection.

Some may feel that I am flogging a dead horse. I agree that the present state of affairs is quite different from what it was fifty years ago. The infant-mortality rate at Paddington is now 29, and marasmus is rarely seen, although occasionally pyloric obstruction is still overlooked to remind us of it. "Infantile dyspepsia," however, still exists, and the danger of overfeeding continues to be emphasised by many. It is my experience, as an examiner at university finals and in the recent past at the D.C.H. examination, to be told by candidates that overfeeding is much more common than underfeeding. Half-cream dried milk—which is nothing more or less than dried skimmed milk—is recommended for healthy infants under the age of 3 months, and partially digested milk foods are still considered helpful. At my own clinics underweight babies who are vomiting, constipated, passing abnormal stools, or not progressing are referred to me as cases of fat-intolerance, pyloric stenosis, or gastro-enteritis; and contact with young postgraduates produces the strong impression that they look on infant feeding as a hazardous business, with the risk of overfeeding and the production of "infantile dyspepsia" and fat-intolerance as the dangers most to be feared.

PRINCIPLES OF INFANT FEEDING

After more than forty years' experience of children's practice and university teaching I should like to offer to others the following principles of infant feeding.

(1) *Generous feeding is essential*

I used to teach that the human infant should double his weight in six months. I soon realised that many healthy breast-fed babies nearly treble their weight in this time. The baby who weighed 7 lb. at birth is a poor specimen if only 14 lb. at six months. Thirty years ago I taught my students that the baby required $2^{1}/_{2}$ oz. of breast-milk or its equivalent in artificial food for each pound of body-weight. Twenty years ago I taught that the infant required $2^{1}/_{2}$ oz. of breast-milk or its equivalent for every pound of *expected* weight—i.e., the weight that the particular infant should have reached if progress had been normal. Still later I felt that this quantity was minimal, and today I am inclined to throw aside all these standard quantities and to allow the infant to have what he or she will take. The practice of "following the baby" is sound, because we can never be sure what a particular infant needs. Those infants who are well down in weight for their age certainly will take an amount of daily food far in excess of minimum requirements, and they continue to do so until they have "taken in the slack." To me it is fundamental that this rapid growth of tissue during the early months of life must be met by generous feeding. If this point is conceded, I submit that Nature would never have provided an infant with a digestive system so delicately balanced that overfeeding or risk of death from harm or illness produced by the food itself could be a possibility. The evidence demonstrates beyond reasonable doubt that starvation and underfeeding in any degree are the dangers most to be avoided and against which the infant has no defence.

(2) *Most babies will progress satisfactorily on the most diverse types of food, so long as the food given is adequate in quantity and well concentrated and can be taken easily by the baby*

All of us agree that breast-milk is the ideal food for the infant. If, after patient trial, breast-milk is found insufficient, the feeds must be supplemented by additional milk food given from a bottle. It is quite wrong, and indeed cruel, to deny an infant additional food because of the mistaken idea that there is something immoral or harmful in making use of some other milk. The proof of the pudding is in the eating, and, if progress is not being made when the child is fed entirely by the mother, something should be done about it at once. There is nothing harmful in "breast and bottle," but everything may go wrong if the feeding technique is at fault. Those doctors and nurses who suggest that breast-milk has "gone off" or is poor in quality are hardly ever right, and the possibility of breast-milk being the cause of "dyspepsia," "colic," or loose stools may be discounted.

Overfeeding at the breast is considered by many to be of common occurrence. This has not been my experience, and indeed I believe it to be exceptionally rare; but underfeeding is only too common. The amount taken at a feed may vary greatly, and a month-old infant may take anything from 2 to 6 oz. Babies are not like penny-in-the-slot machines, and I feel sure that we have done harm in insisting on exact quantities, exact times, and feeding by the clock. Once upon a time there were no clocks, and the untutored mother of the past—like that of the present—would never dream of waking her baby out of sleep to administer another feed. From the mother's point of view regularity is something to be striven for. My own practice has been to begin feeding babies three-hourly for six feeds a day. Where sleep is sound and progress satisfactory the feeds may be four-hourly or thereabouts. The infant must not be encouraged to feed between 10 P.M. and 6 A.M., but if he is wakeful and hungry it is foolish not to give food. We should aim at sufficient food by day to prevent hunger and wakefulness at night. I appeal for far more common sense and less adherence to regulations. Let us rely more on the mother and on her attitude and feelings towards her baby, for by so doing we shall engender an enhanced degree of confidence in herself.

When the bottle is used as complementary to the breast, or when breast-milk is not available, the "bran-tub" method of trying to find a suitable food is wrong. The ideal alternative continues to be boiled fresh milk with added sugar. My practice has been to order a 4 : 1 mixture, with the addition of a large flat teaspoonful of sugar—'Dextri-Maltose' is particularly suitable—to every 4 oz. Such a mixture can be given without alteration up to the age of weaning. The defect with cow's milk is the shortage of sugar. I have never been convinced that healthy babies suffer from fat intolerance when a "milk, water, sugar" mixture is used, nor does sugar in the quantity recommended cause acid stools.

There are, however, situations and occasions when a dried milk is the better choice. A whole-cream dried milk should be used to which sugar has been added by the makers—'Modilac' (Cow & Gate) and 'Ostermilk no. 1' (Glaxo) are suitable—or sugar can be used with National Dried Milk.

The feeding of healthy babies with a half-cream dried milk cannot be too strongly deprecated. This is feeding with skimmed milk. I feel sure that those who recommend it would be shocked to hear of anyone feeding healthy infants with fresh skimmed milk. Its use seems to imply that healthy infants during the early months of life cannot digest the amount of fat in a simple "milk, sugar, water" mixture, and that "dyspepsia" will result. We should remember that if, before the milk is dried, part of the fat is removed, the resulting powder will be relatively heavier, and the space taken up by the protein in the packet will be much greater to fill the space produced by the removal of fat; if sugar has been added by the manufacturers, the relative amount of fat will be still further reduced. Those, therefore, who favour the routine feeding of healthy infants during the early months with a half-cream preparation are providing the infant with a much reduced fat ration and at the same time are giving the infant an amount of protein and nitrogenous material in excess of that in fresh whole milk, although most authorities agree that the modification of cow's milk to reduce the excess of protein is desirable.

(3) *The symptoms of "infantile dyspepsia" are generally caused by mistakes in feeding technique*

The main causes of vomiting, posseting, infrequent or abnormal stools, "colic," "wind," and excessive crying during the breast- or bottle-feeding period may be summarised as follows:

Underfeeding due to the fear of overfeeding.

Strict adherence to the quantities indicated by academic dictates.

Feeding according to *present* weight rather than *expected* weight.

Following the directions set out on the packet of dried milk. These are usually calculated for an infant whose birth weight was $6^{1}/_{2}$ lb.

Feeding all infants four-hourly from the start.

Using a bottle open at one end only.

Using a teat which will not allow an easy flow of milk or which collapses in the infant's mouth like blotting-paper, either because of age or continual boiling.

Allowing the infant to feed for twenty minutes or longer.

Administering quantities of water and glucose solution between the feeds.

Making the feed too hot (I have twice seen a baby scalded about the face and neck by the contents of the bottle).

Misinterpreting the symptoms as those of subacute gastro-enteritis, and treating and feeding accordingly.

VOMITING, POSSETING, AND REGURGITATION

At the outset I spoke of the importance, when an infant begins to return his food, of making sure that there is no congenital obstruction and that he has no acute sudden illness such as gastro-enteritis or whooping-cough.

Most infants who bring their food back do so because they have learnt during the early weeks of life to suck air when feeding from the breast. When a mother breast-feeds the baby and has adequate milk which comes easily, the baby is satisfied in about seven minutes. Allowing the baby to continue sucking from the empty breast, or from a bottle from which he cannot easily get the milk, is a common cause of excessive air-swallowing. If, therefore, the infant is still willing to suck from breast or bottle at the end of twenty minutes, either there is insufficient milk to satisfy him or he cannot get it. This habit of excessive air-swallowing, which so often is the cause of vomiting and posseting, may be easily acquired, even during the early days and weeks of life, and once learnt is not readily given up.

Vomiting may be explosive, but often there is also a more or less continuous return of a few mouthfuls of very acid curdy fluid. To this the word "posseting" has been given, and, rarely, such an infant may have a congenital muscular defect of the lower end of the œsophagus which allows stomach contents to "well up" into the œsophagus during contractions of the stomach. Most posseting infants, however, learn the habit of bringing their food back (rumination) and enjoy the experience of so doing. Normal babies are hungry babies whose only object in life is to get food, and if they are not fully satisfied they will resort to this regurgitation or rumination—even the very young ones will do this—so as to experience the pleasure of going through again that which they have managed to take.

I do not myself believe that the return of food, which has so often in the past been explained on the basis of overfeeding and fat intolerance, has anything to do with either of these supposed causes. Some babies do, no doubt, return a few mouthfuls of milk after a feed, and may continue to behave in this way until they reach the age of weaning, but to label such babies as dyspeptic is, I feel sure, wrong. Clean wholesome milk food does not and cannot produce dyspepsia, colic, wind, or excessive acidity. It is a continuing insufficiency in volume or quality which so often causes harm. The repeated return of acid material by the unsatisfied baby is due to expectancy, hunger, and nervous upset causing a free secretion of gastric juice which is not used up by a full-strength feed. Much the same thing happens when a baby soils a napkin at every feed. Its eagerness to get food leads to active peristalsis and a bowel movement at the time of a feed.

SCREAMING, EXCESSIVE CRYING, "COLIC," AND SLEEPLESSNESS

Air-swallowing probably causes some discomfort. It may certainly produce abdominal distension, and very possibly the swallowed air will pass into the bowel and produce disturbances in peristaltic action. If this happens, the child may cry. When we are told by mothers that an infant screams, draws up its legs, and has "colic," we must be careful not to accept this interpretation of the screaming too readily. Who can be sure that a baby is in pain? By far the most likely explanation is that the screaming and so-called colic are due to hunger, frustration, and nervous upset. My advice to those who doubt this is to try the experiment of giving such an infant a generous feed, ensuring that he can get it easily and is fully satisfied. Quick feeding —ten to twelve minutes as a maximum—does much to prevent excessive air-swallowing.

ABNORMAL AND EXCESSIVE NUMBER OF STOOLS

The stools of normal infants progressing satisfactorily may vary in number from 3 a week to 6 or 7 in twenty-four hours. It is not uncommon for a breast-fed baby who is putting on weight normally to produce only 2 or 3 stools a week, and such stools are normal in consistence and colour and not dry, hard, and pellety like the stools of some bottle-fed babies. With bottle-fed babies infrequent stools may be due to lack of food, but part of the infrequency results from the consistence of the stool—the so-called soap fat stool—which is not unusual when cow's milk, dried or fresh, is given.

The hungry, eager, sleepless, and nervously upset baby may have a stool with every feed, and such stools may be green, liquid, curdy, and of abnormal colour and odour. Intestinal juices are actively secreted, peristalsis is vigorous, and the condition is not unlike the so-called lienteric diarrhœa of older infants and children. At one time I used to take a great interest in the stools and went so far as to make coloured drawings of them and have their exact numbers recorded by the nurses: if they were too frequent or abnormal, the feeds would be cut down and the proportion of the different ingredients altered—fat or sugar would be lowered or the food predigested, and so on—but I have for a long time given this up. Now I am more interested to watch the infant to see that he is satisfied. Over and over again one has seen the stools of a restless hungry infant become normal in number and consistence merely by increasing the food, which must be well concentrated, properly measured and taken in adequate amounts, from a boat-shaped bottle through an easy teat. It has often amused me to watch doctors awaiting the return of an infant's stools to normal while the baby is being given quantities of glucose substance, or a weakened feed which could not possibly produce a normal stool. It should also be remembered that redness and rawness around the anus is by no means a certain sign of bowel infection: indeed, babies with gastro-enteritis do not often have soreness in this area. On the other hand, intestinal juices which, owing to hunger, nervous upset, and overactive peristalsis, have been passed through the bowel too quickly and have not been used up in the digestion of food may cause anal irritation and soreness, and this may happen even in the neonatal period.

ENVOI

The feeding of a baby is not always straightforward, even when technique is satisfactory and adequate food is supplied which the child can easily get. The risk of infection is always in the offing, especially in institutional practice. When once an infant has developed an infection of the nose, nasopharynx, ear, bronchial tubes, or urinary or intestinal tract, the ability to take food and to absorb it may be temporarily and sometimes severely reduced. Breast-feeding may break down completely when an infant in the early days and weeks of life develops acute dry or moist rhinitis. A *stomatitis* due to thrush or streptococcus may mean the refusal of feeds and loss of weight, followed by œsophagitis which may cause considerable vomiting and lead on to marasmus. A true gastro-enteritis infection may result in serious nutritional breakdown. Listlessness and refusal to feed may be due to the infant's becoming chilled, as proved by the rectal temperature failing to register above 97°F. Repeated infections may lead to the marasmic state, and the more severe the grade of marasmus the less is the ability to tolerate food of any kind. (It would indeed by quite imposible for an infant with advanced marasmus during the days preceding its death to take and absorb the amount of food suited to its expected weight.) All these conditions therefore require their proper prevention and management; but they do not in any way invalidate the truth of the principles which I have submitted—namely, that the food itself is not the cause of "infantile dyspepsia," and that babies must be generously fed.

THE MANAGEMENT OF AN ILEOSTOMY INCLUDING ITS COMPLICATIONS

B. N. Brooke
M.Chir. Camb., F.R.C.S.
READER IN SURGERY IN THE UNIVERSITY OF BIRMINGHAM

An ileostomy must work perfectly if the surgical treatment of ulcerative colitis is not to fall into disrepute; the closest attention must therefore be paid to the minutiæ of technique and to subsequent care.

The ileum should be divided and the ends separated so that the functioning stoma presents as a terminal vent about $1-1^{1}/_{2}$ in. long (Hardy et al. 1949). A loop ileostomy is still regarded by some surgeons as justifiable in a serious case (Lahey 1951); but it should be avoided if possible, because an ileostomy bag cannot be applied effectively to it. Where a primary colectomy without pre-existing ileostomy is done, the terminal ileum forms the stoma, and the same principles apply.

ILEOSTOMY BAGS

Generally an ileostomy acts after meals and during the night, though some of the contents of the small bowel may be voided at any time. It must not be thought that one type of bag suits all patients—indeed a few prefer the old rigid cup appliance—but usually the Koenig-Rutzen type of bag is most favoured, and most makes of bag act on the same principle of adherence to the skin, from the simple disposable type to the more complicated kind in two pieces with an adherent flange and removable bag.

The cement or glue is not always satisfactory, but this is occasionally the fault of the patient, who is unaware that it should not be applied too liberally to the flange of the bag, and that the flange should not be pressed on to the skin until the cement begins to become tacky—just like mending a puncture. If the glue fails, further support and a more perfect seal can be obtained by strapping the flange to the abdominal wall with a waterproof adhesive—e.g., 'Sleek.'

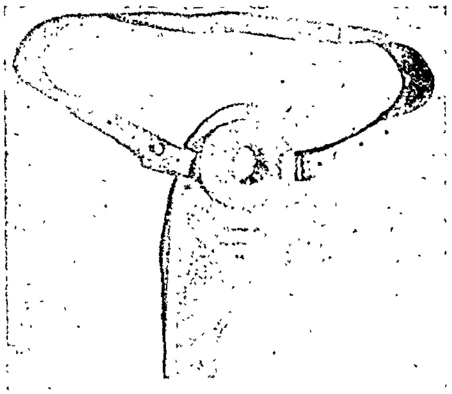

Fig. 1—Koenig-Rutzen bag with belt.

A collar can be placed in the neck between bag and flange and attached to a light belt to give patients an added sense of security; or an elastic corset can be worn with a hole cut to accommodate the bag. A belt is attached to the flange of some bags (fig. 1), but this tends to interfere with an adhesive seal.

A bag seldom sticks firmly from the outset, and there is often a tendency to leak on the outer side during the first month or two. This naturally disappoints the patient, who should be reassured, for, if the stoma has been placed correctly, the leak will cease as the patient puts on weight and the gutter between stoma and anterior superior iliac spine fills up. There is a further tendency to leak at night, for recumbency causes the ileal contents to form a pool over the stoma instead of draining into the bag; the leak occurs on the lateral side and is controlled by reinforcement with adhesive.

Most patients remove the bag once or twice daily, but it can be worn without change for longer periods—even up to a week. Odour is hardly noticeable, since the contents of the ileum are inoffensive and do not react with rubber in the same way as those from the large bowel. Most rubber bags require renewal after 4–6 months, though some patients seem able to maintain them in adequate repair for a longer time.

EXCORIATION

Excoriation of the skin often develops round the ileostomy and may last for six weeks after the operation. Once the skin heals, the trouble seldom recurs; but one woman reported repeated excoriation at the time of her periods, and another developed skin sensitivity to the cement three years after operation. A faulty stoma, or a fistula which constantly discharges at skin level, will induce persistent ulceration; similarly a persistent retrograde discharge of pus will damage the skin round the distal stoma.

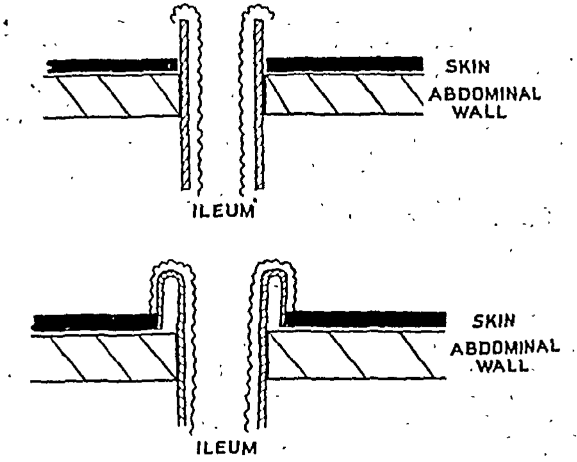

Fig. 2—Usual ileostomy (above) and ileostomy with everted end (below).

Several factors seem to contribute to this, chief of which are the continuous moisture and the trauma resulting from repeated application of the bag. Theoretically, responsibility might rest with the proteolytic enzymes sometimes present in the ileal contents, for they act upon denatured protein and could therefore digest the outer layer of the skin. However, no correlation has been found between the presence of enzyme and excoriation; wetting agents, such as cetyl sulphate, which destroy enzyme activity have not given complete protection to the skin, and the application of dressings containing ileal contents have not caused excoriation in areas remote from the ileostomy, even when ulceration has been present round the stoma.

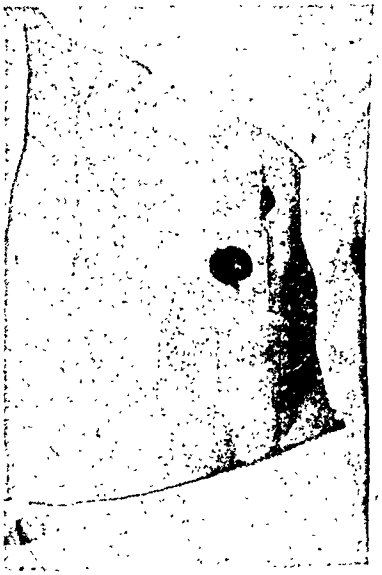

Fig. 3—Everted ileostomy, with mucosa sutured to skin, immediately after operation.

It is helpful to obtain drainage into a bag from the

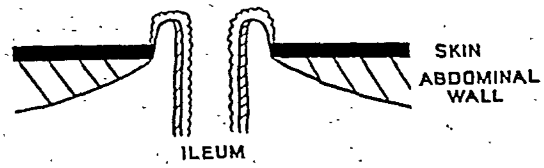

Fig. 4—Prolapse starting as herniation owing to damage to abdominal wall (cf. fig. 2).

outset and, to avoid the shearing effect of the adherent flange on the outer layers of constantly moist skin, it is best to build up a pad of gauze round the stoma for the flange to rest on. Both flange and dressing are next sealed off with adhesive, which adheres to the skin where it is not affected by ileostomy drainage. Protection in this manner may continue for two or three weeks after operation, by which time it should be possible to start using the cement.

Where excoriation persists because an inefficient stoma discharges its contents at skin level, only further operation and refashioning of the ileostomy will bring about any improvement; to rely on dressings and ointments in such cases is only to encourage vain hope.

INTESTINAL OBSTRUCTION

Intestinal obstruction is the commonest serious complication of ileostomy, but not much has been published about it. Warren and McKittrick (1951), however, have given a good account of it, using the title "ileostomy dysfunction" for the particular syndrome arising from partial obstruction which more often occurs; it was a major complication in 61·9% of their 210 patients. In my series of 37 ileostomies there have been 10 cases of obstruction, 1 causing the death of the patient, 2 requiring laparotomy for relief of adhesions, and 7 recovering without operation. Obstruction has not followed ileostomy done as part of the operation of primary colectomy in 9 further cases.

The site of obstruction may be at the stoma, at the abdominal wall, or within the abdomen owing to internal herniation or to adhesions. (Stenosis of the stoma is considered below.) If any part of the abdominal wall, especially the anterior rectus sheath or external oblique aponeurosis, is sewn with tension round the emerging ileum, this may precipitate obstruction in the relatively adynamic phase which follows the operation; it is avoided by relieving incisions in these structures. Likewise obstructions from snaring in the para-ileal gutter or at the site of mesenteric fixation (Hardy et al. 1949) is due to technical failure and can be avoided. It may even be that the fine adhesions which cause angulation and fixation of normally mobile small bowel (Brooke 1951) can be prevented; in the last 9 cases streptodornase and streptokinase have been injected into the peritoneal cavity in the hope of preventing the formation of these adhesions, and no obstruction has arisen in these 9 cases compared with an incidence of 1 in 3 before this.

The treatment of obstruction has been discussed elsewhere (Warren and McKittrick 1951, Brooke 1951) and needs no further mention here.

STENOSIS

Stenosis at the stoma arises, as Warren and McKittrick (1951) state, from scar tissue formed by the granulations that cover the raw serosal surface of the protruding ileum during the two postoperative weeks before the gradual evagination of the mucosa has brought that surface into continuity with the skin edge. It has complicated 4 of the 37 cases previously mentioned. Skin grafting (Dragstedt et al. 1941) should eliminate this but has not always proved satisfactory; for the graft, whether it be full-thickness or split-skin, is not infrequently followed by ulceration, stenosis, and even a fistula, though it is only fair to say that these difficulties have not been encountered at the Mayo Clinic (C. W. Mayo, personal communication).

Wells (1952) describes a "spout" ileostomy and states that the results are good, but his report is couched only in very general terms. A more simple device is to evaginate the ileal end at the time of operation and suture the mucosa to the skin (figs. 2 and 3); no complications have accrued from this. For the first few days the "bud" appears flattened on the skin, but it does not retract and should not do so if the mesentery has been tethered to the anterior abdominal wall; it soon stands out in conical form. Prolapse, which might be expected to follow this manœuvre, has not been encountered.

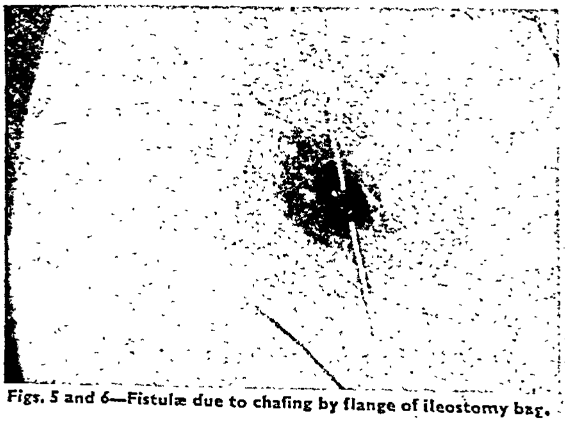
When stenosis develops it can sometimes be relieved by simple dilatation but may necessitate operation for its relief. It occasionally presents as retraction of the "bud"; in these cases contraction of the bowel wall causes the stoma to be withdrawn below the constriction, from which it cannot escape.

Fig. 5.

PROLAPSE

Prolapse, in the experience of most workers in this field, is a common complication—13% according to Warren and McKittrick (1951). In my series of 37 ileostomies 2 have prolapsed, and none of the 9 primary colectomies have given trouble in this way.

To prevent this complication the first principle is to fix the mesentery, as has been described elsewhere (Hardy et al. 1949, Brooke 1951). Mesenteric fixation will not, however, secure the bowel if the abdominal wall round the stoma has been damaged by infection or by further operation. In these circumstances the abdominal wall adjacent to the ileum becomes thin and fibrotic, and the gap through which the ileum passes widens so that



Figs. 5 and 6—Fistulæ due to chafing by flange of ileostomy bag.

herniation inevitably ensues; herniation thus initiates this type of prolapse (fig. 4). It is significant that 1 of the 2 cases of prolapse occurred after colectomy when the mesentery of the emerging ileal limb became detached and was not sutured down; this was cured by refixing the mesentery. In the other case prolapse followed a revision of the ileostomy for fistula; this was cured by removing the ileostomy stoma to a site where the tissues of the abdominal wall were undamaged.

The herniation type of prolapse can sometimes be controlled by pressure from outside the bag through a pad held opposite the stoma, but this will not prevent most cases of prolapse, for these develop as a form of intussusception. The operation, so commonly done for prolapse, of simply lopping off the extruded bowel is to be condemned outright. It is quite indefensible for two reasons: (1) it does not cure the prolapse, which almost invariably recurs; and (2) it removes an absorptive area of the bowel, every inch of which the patient requires.

For the operative cure of prolapse the abdomen should be opened through an incision remote from the ileostomy, which is then inspected from within as well as outside. If it is found by palpation that the abdominal wall alongside the ileum is attenuated, or that a finger passed from inside the abdomen presents at the stoma submucosally (fig. 4), the ileostomy should be detached and drawn out through a stab incision elsewhere, and finally the mesentery should be attached with care across the para-ileal gutter. If the ileum is discovered to be adherent throughout the depth of the abdominal wall in the normal way, mesenteric fixation with non-absorbable sutures should suffice.

FISTULÆ

Fistulæ form for two reasons. The ileal wall may be damaged or weakened at the time of operation; a fixation suture through serosa and muscle alone without penetration of the mucosa is particularly liable to cause a subsequent breakdown of the whole thickness of the bowel wall. A suture or ligature lying close to the ileum but not penetrating it in any way can lead to the same result. In these circumstances the fistula will appear in the first ten days or so after the operation. A fistula at skin level develops at any time after the operation through chafing of the stoma against the flange of the bag (figs. 5 and 6). The site of this fistula is inferior, and the fistula is probably caused where a stoma is placed too close to the groin, with the result that the flange is pushed up against the stoma when the patient sits down. It is also more liable to occur when the flange is reinforced with metal.

Fistulæ are avoided therefore by the elimination of fixation sutures, by suturing without tension the structures round the ileum, and by the proper siting of the stoma; it is also advisable not to use a bag with a flange reinforced with metal. The formation of a new ileostomy by further operation is the only cure for either type of fistula, and this must be done because persistence of a fistula, even though it may not pass deep to the skin, will cause excoriation and render the bag inefficient.

I wish to thank Dr. H. G. Sammons, of the department of pharmacology, University of Birmingham, for assessing the proteolytic activity of ileal discharges.

ANTIBIOTICS AND AMŒBIC DYSENTERY

R. ELSDON-DEW
M.D. Witwatersrand

T. G. ARMSTRONG
M.A., M.D. Camb., M.R.C.P.

A. J. WILMOT
D.M. Oxfd, M.R.C.P.

From the Amœbiasis Research Unit of the Council for Scientific and Industrial Research, Durban

IT has been known for many years that the ingestion of *Entamœba histolytica* does not necessarily mean that the patient will have either dysentery or any other manifestation associated with this parasite. The classical experiments of Walker and Sellards (1913) showed that only a proportion of volunteers deliberately infected with *E. histolytica* developed dysentery, although the infestation was well established. Westphal (1937), who infected himself with washed cysts from a case of dysentery, did not develop symptoms until he followed his diet of amœbæ with one of the associated fæcal flora from the same case. Differences in associated bacterial flora have been used by many workers, notably Deschiens (1937), to explain the difference in incidence of acute amœbic dysentery in warm and in temperate zones. Mathis (1918) stated that a bacterial flora adapted to a tropical humid climate might in a person coming from the temperate zones create conditions favourable for the development of the "aggressive" amœba. Conversely it has been the experience of doctors working in the tropics that spontaneous remissions in chronic amœbiasis can occur on transfer to a temperate zone.

Knotts and Thompson (1942) used an antibacterial approach to the treatment of amœbiasis in 1942, when they treated six cases of proved amœbiasis with success.

Payne (1945) found both sulphapyridine and sulphaguanidine clinically effective.

Hargreaves (1944) reported that penicillin was effective in saving the life of a moribund patient with dysentery, and he later (Hargreaves 1945) reported the successful use of penicillin and succinyl sulphathiazole in conjunction with emetine, bismuth iodide, and chiniofon.

Blanc and Siguier (1946), working in Indo-China, reported very favourably on the use of emetine, penicillin, and sulphaguanidine.

Halawani et al. (1946), in Egypt; Achitouv-Verdi (1945), in Turkey; Ellenberg (1946), in the United States; and Karl and Sloan (1946), in the India-Burma theatre of war, all reported on the value of sulphonamides as adjuvant treatments.

Armstrong, Wilmot, and Elsdon-Dew (1949) were impressed with the results of the treatment with penicillin, succinyl sulphathiazole, emetine, and 'Diodoquin,' and Armstrong, Marot, and Elsdon-Dew (1950a) reported on the value of penicillin alone and of succinyl sulphathiazole alone.

The next advance was published by McVay et al. (1949, 1950), who reported the effectiveness of aureomycin by itself.

Almost simultaneously Hughes (1950), Gutch (1950, 1951) and ourselves (Armstrong et al. 1950b) published further results indicating the effectiveness of aureomycin in the treatment of amœbiasis. Though these workers all reported relapses, there were indications that aureomycin had a directly amœbicidal action in addition to the bacterial sterilising effect on the bowel reported by Dearing and Heilman (1950).

Jones (1950) pointed out the difficulties in distinguishing such anti-amœbic from antibacterial effects in vitro. These difficulties were largely overcome by Hewitt et al. (1950), who showed that exposure of amœbæ to aureomycin for an hour was sufficient to prevent growth after adequate washing and reseeding under ideal conditions.

The next antibiotic to enter the field was bacitracin.

Most et al. (1950b) reported that there was complete recovery, with disappearance of amœbæ, in 8 severe cases, and 66% of mildly symptomatic or asymptomatic patients who received the treatment were cleared. Most et al. (1950a compare aureomycin and bacitracin and mention that chloromycetin was usually found ineffective.

Next, Most and van Assendelft (1950) reported on the effects of terramycin, which they found completely effective in 21 out of 22 cases. In a further paper (1951) they report results in 54 cases and point out that the optimal dosage is 2 g. a day for ten days.

The adequacy of this form of treatment was confirmed by Nor-El-Din (1951), in Egypt, who reported complete cure with two relapses, one after a month and another after six weeks. After treating 9 monkeys under controlled conditions Hrenoff (1951) found relapses in five, nine, and eleven weeks.

Conn (1951), basing his work on that done by Thompson et al. (1950), tried both aureomycin and chloramphenicol. With the former they had 3 failures out of 17, and with the latter 3 failures out of 6.

Felsenfeld et al. (1950) reported that neomycin showed a strong activity in vitro and in vivo against *E. histolytica.*

It will be seen that many different antibiotics and other antibacterial drugs have been tried in amœbiasis, but it is very difficult to compare and contrast the results. The standards of diagnosis, of severity, and of cure vary from one worker to another. Since amœbiasis may vary in its manifestations from complete quiescence to fulminant dysentery, it is impossible to compare the various types of therapy.

METHODS

The high incidence of amœbic dysentery in the Durban African has enabled us to use a statistical approach to assess the results of therapy. We were able not only to use 50 cases as a standard basis for assessment but also to select cases so that the clinical and laboratory manifestations were, so far as possible, uniform. When there was a high failure-rate among the early cases treated with a particular drug and it could be shown statistically that the drug was not likely to be of much value, that series was discarded. Occasionally, shortage of a drug limited the number of cases which could be treated with a particular drug.

All the patients accepted for the trials were complaining of diarrhœa with blood and mucus, showed ulceration on sigmoidoscopy, and had actively motile *E. histolytica* in stools or ulcer scrapings. Patients passing cysts were not accepted. In the Durban African, for reasons which we do not understand, amœbic dysentery tends to be unusually severe. We excluded patients who showed chloride deficiency, abdominal distension, sloughs on sigmoidoscopy, or other signs which we have found to presage perforation or ileus, because we thought it unjustifiable to experiment on such severely ill patients. Any cases showing liver manifestations were also excluded. The cases accepted therefore represent a relatively uniform population.

Sigmoidoscopy was always done before treatment. In the earlier series it was repeated at ten and twenty days, and in the later series at intermediate intervals as well and at twenty-seven days after the start of treatment. With certain drugs sigmoidoscopy was done daily, so that the day of healing and the day of disappearance of amœbæ could be determined. Ulcer scrapings were examined directly. Stools were examined by saline smear, zinc-sulphate flotation, and, where indicated, by staining.

Results were classified into four categories:

(1) *Success:* patient symptom-free; all ulcers healed, and no amœbæ found in stools.

(2) *Probable failure:* patient usually symptom-free; one or more ulcers still open, but amœbæ not found in stools or scrapings.

(3) *Cyst-passer:* patient symptom-free; ulcers healed, cysts present in stools.

(4) *Absolute failure:* open ulcers and/or amœbæ still present.

At the outset of this work we did not know the relative efficacy of even the recognised amœbicides. We therefore tested the known amœbicides separately; but, when later experience indicated that certain additional therapies were likely to be successful, we could no longer risk the lives of patients who were obviously deteriorating. These patients were removed from the series and given additional drugs. Such cases that had had five days or more of a particular test therapy were regarded as failures for that therapy; but, where a case had to be removed from a series before five days of the test therapy, the case was not included, because it was felt that the drug had not had a fair opportunity.

Under the heading "Combined Failure-Rate" we have included all those who still harboured parasites. This figure is the sum of the figures for absolute failures, cyst passers, and those removed from treatment.

Our records are nearly complete as regards immediate result, but our follow-up studies have perforce been very incomplete. The African is careless of his health and sees little reason to return for follow-up if he is well. Since few of our patients have permanent addresses, it is impossible to re-establish the contact broken on discharge, and we have to rely only on the individual goodwill of patients for follow-up studies. Even with a bribe coöperation has been poor. Though we have little evidence on the presence or absence of amœbæ as time passes after the end of treatment, we have some evidence on the incidence of symptomatic relapse. Our patients are very satisfied with the attention paid to them, and most of them return to us if symptoms recur. We are therefore in a position to give the figures of relapse or reinfection in those who return to us. Probably this figure is a reasonable approximation of symptomatic relapse and comparable from one series to another. This is, of course, a minimal clinical and parasitic relapse-rate, which leaves out the few who go elsewhere and all cases of parasitic relapse without symptoms.

RESULTS

Procaine Penicillin

Details of this series of 54 cases were given in a previous paper (Armstrong et al. 1950a). The dosage was 300,000 units in oil daily for twenty days (total 6,000,000 units). By the twentieth day there was considerable improvement in all the cases, and in 39% all visible ulcers had healed and amœbæ had disappeared (table I). Even without further treatment there was still improvement between the twentieth and twenty-seventh days, and at this stage 46% of the cases had been cleared of their ulcers and amœbæ.

TABLE I—RESULTS WITH PROCAINE PENICILLIN 300,000 UNITS IN OIL DAILY FOR TWENTY DAYS (TOTAL 6,000,000 UNITS)

Assessment	No. of cases (total 54)		
	At 10 days	At 20 days	At 27 days
Successes	12 (*22·2%*)	21 (*38·9%*)	25 (*46·3%*)
Probable failures	16 (*29·6%*)	12 (*22·2%*)	9 (*16·7%*)
Cyst-passers	Nil	Nil	Nil
Absolute failures	26 (*48·2%*)	19 (*35·2%*)	8 (*14·8%*)
Removed from treatment	Nil	2 (*3·7%*)	12 (*22·2%*)
Combined failure-rate	48·2%	38·9%	37·0%

Of 15 cases that had not responded to penicillin 11 improved greatly on succinyl sulphathiazole, and 7 of these were classified as successes. However, 1 of these so-called successes returned fourteen days later and quickly died of a fulminating amœbic colitis, providing tragic proof that we had neither eradicated the parasite nor permanently curbed its powers of invasion.

Succinyl Sulphathiazole

The dosage in these 57 cases was 15 g. initially, followed by 3 g. four-hourly five times a day. This dosage is double that given by Hargreaves (1945) in his original course, and was continued for twenty days instead of 7.

TABLE II—RESULTS WITH SUCCINYL SULPHATHIAZOLE 15 G. INITIALLY, FOLLOWED BY 3 G. FOUR-HOURLY FIVE TIMES A DAY FOR TWENTY DAYS (TOTAL 315 G.)

Assessment	No. of cases (total 57)		
	At 10 days	At 20 days	At 27 days
Successes	9 (*15·8%*)	22 (*38·6%*)	31 (*54·4%*)
Probable failures ..	26 (*45·6%*)	15 (*26·3%*)	9 (*15·8%*)
Cyst-passers	Nil	Nil	Nil
Absolute failures ..	21 (*36·8%*)	18 (*31·6%*)	4 (*7·0%*)
Removed from treatment	1 (*1·8%*)	2 (*3·5%*)	13 (*22·8%*)
Combined failure-rate..	38·6%	35·1%	29·8%

Throughout this series, as in that treated with penicillin, there was a steady fall in the number of failures and as steady a rise in the number of successes even after treatment had ceased (table II).

It is particularly worthy of note that after only ten days' treatment with succinyl sulphathiazole 62·5% of these patients had been rendered free not only of their symptoms but also of their amœbæ. This is a matter of first importance and indicates the danger of treating cases of undiagnosed dysentery with sulphonamides. Such a practice would lead to the suppression of the correct diagnosis in many cases of amœbic dysentery.

Procaine Penicillin and Succinyl Sulphathiazole

The results (table III) show that these two substances have a synergistic effect. Of the 50 patients only 3 showed parasites on the twenty-seventh day, and 1 of these was a symptomless cyst-passer. When it is remembered that neither of the drugs used is considered to have any action other than antibacterial, the results are remarkable.

TABLE III—RESULTS OF COMBINED TREATMENT WITH PROCAINE PENICILLIN AND SUCCINYL SULPHATHIAZOLE

Assessment	*No. of cases (total 50)*		
	At 10 days	At 20 days	At 27 days
Successes	34 (*68%*)	43 (*86%*)	46 (*92%*)
Probable failures ..	15 (*30%*)	6 (*12%*)	1 (*2%*)
Cyst-passers	Nil	Nil	1 (*2%*)
Absolute failures ..	1 (*2%*)	Nil	1 (*2%*)
Removed[1] from treatment	Nil	1 (2%)	1 (2%)
Combined failure-rate..	2%	2%	6%

Phthalylsulphacetamide

A series was begun in which treatment was with phthalylsulphacetamide 3 g. four-hourly five times a day for twenty days (total 300 g.). When only 12 cases had been completed, it was apparent (table IV) that, in this dosage, this sulphonamide was inferior to succinyl sulphathiazole; so there was no point in investigating it further.

Streptomycin

The dosage in 17 cases was 2 g. daily by mouth for ten days (total 20 g.). It will be seen from table V that it was necessary to remove 7 of the cases from the therapy before the test period had elapsed. Streptomycin manifested an unusual feature: at one time or another during the course of the therapy no fewer than 8 of the 17 cases passed cysts, a phenomenon seen before in isolated cases only.

TABLE IV—RESULTS WITH PHTHALYLSULPHACETAMIDE 3 G. FOUR-HOURLY FIVE TIMES A DAY FOR TWENTY DAYS (TOTAL 300 G.)

Assessment	No. of cases (total 12)	
	At 10 days	At 20 days
Successes	Nil	2 (*16·6%*)
Probable failures	4 (*33·3%*)	2 (*16·6%*)
Cyst-passers	Nil	Nil
Absolute failures	8 (*66·6%*)	8 (*66·6%*)
Failure-rate	66·6%	66·6%

Aureomycin by Mouth

This series has been discussed at length elsewhere (Armstrong et al. 1950b) and the results are shown in table VI. The rather small dose of 1 g. was given daily for fifteen days to 52 patients. Daily sigmoidoscopy showed a remarkably rapid rate of healing. 12 cases (24·9%) were healed by the fourth day, and 29 (55·7%) by the seventh day. Disappearance of amœbæ was equally rapid. By the fourth day 71%, and by the ninth day 98%, of patients had been cleared of amœbæ. It was found in most cases that on the third and fourth days the amœbæ increased greatly in size, sometimes reaching a diameter of 90 µ. A day later they had usually vanished.

TABLE V—RESULTS WITH STREPTOMYCIN 2 G. DAILY FOR TEN DAYS

Assessment	No. of cases (total 17)		
	At 10 days	At 20 days	At 27 days
Successes	5 (*29·4%*)	4 (*23·5%*)	4 (*23·5%*)
Probable failures ..	4 (*23·5%*)	2 (*11·8%*)	1 (*5·9%*)
Cyst-passers	2 (*11·8%*)	3 (*17·6%*)	2 (*11·8%*)
Absolute failures ..	6 (*35·3%*)	2 (*11·8%*)	3 (*17·6%*)
Removed from treatment	Nil	6 (*35·3%*)	7 (*41·2%*)
Combined failure-rate..	47·1%	64·7%	70·6%

It was necessary to remove only 1 case from this series owing to deterioration. Within a month of completion of treatment 6 of our patients, classed as successes, had relapsed with proved amœbic dysentery and 1, though symptom-free, had cysts in his stools. This cyst-passer was symptom-free and normal on sigmoidoscopy, with a negative casual stool, at seven months. 20 successes were seen at one month, 8 at two months, 2 at three months, and 1 at four months. 1 patient was readmitted at eleven months with clinical dysentery. 1 was symptom-free at eleven months, and another at sixteen and a half months.

Intravenous Aureomycin

We gave aureomycin intravenously to 2 cases:

CASE 1 received 300 mg. twelve-hourly for eleven doses. At the end of this time the aureomycin was stopped because all the ulcers had healed. Trophozoites disappeared on the fourth day, and all the ulcers were healed on the fifth day. Cysts were present on the seventeenth, eighteenth, and nineteenth days, though all the ulcers remained healed on the tenth, fifteenth, twentieth, and twenty-seventh days. Five weeks later, though the patient was symptom-free, open ulcers and trophozoites were present.

TABLE VI—RESULTS WITH ORAL AUREOMYCIN 1 G. DAILY FOR *FIFTEEN DAYS*

Assessment	No. of cases (total 52)		
	At 10 days	*At 20 days*	*At 27 days*
Successes	35 (*67·3%*)	49 (*94·2%*)	48 (*92·3%*)
Probable failures ..	16 (*30·8%*)	2 (*3·8%*)	2 (*3·8%*)
Cyst-passers	Nil	Nil	Nil
Absolute failures ..	1 (*1·9%*)	1 (*1·9%*)	1 (*1·9%*)
Removed from treatment	Nil	Nil	1 (*1·9%*)
Combined failure-rate..	1·9%	1·9%	3·8%

CASE 2 received 300 mg. twelve-hourly for eight doses. All the ulcers were healed by the fourth day, and trophozoites disappeared on the third day. No ulcers were seen up to the twenty-seventh day, but cysts were *found on the* twentieth

TABLE VII—RESULTS WITH TERRAMYCIN 1 G. DAILY FOR FIFTEEN DAYS

Assessment	No. of cases (total 49)		
	At 10 days	At 20 days	At 27 days
Successes	43 (*87·7%*)	44 (*89·8%*)	45 (*91·8%*)
Probable failures	4 (*8·2%*)	2 (*4·1%*)	Nil
Cyst-passers	Nil	Nil	Nil
Absolute failures	2 (*4·1%*)	1 (*2·0%*)	Nil
Removed from treatment	Nil	2 (*4·1%*)	4 (*8·2%*)
Combined failure-rate	4·1%	6·1%	8·2%

and twenty-seventh days. Four weeks later the patient had diarrhœa, and trophozoites and ulcers were found.

Terramycin

Terramycin 1 g. daily in divided doses was given to 49 patients (table VII). There were originally 51, but 2 developed hepatitis which progressed in spite of terramycin treatment and necessitated the use of emetine on the sixteenth day in one case and chloroquin on the sixth day in the second. Both cases were "successes" from the intestinal standpoint before the extra drugs were used. It was decided, however, to discard them from the series as not conforming to our usual standard. Follow-up was, as always, very incomplete. At one month 20 cases returned, 18 being successes and 2 failures in full relapse. At two months there were 4 successes and 1 failure. At three and four months there were 3 and 1 successes respectively. At six months 1 absolute failure returned. At eight months 1 success returned. From the follow-up figures available to us it is not possible to compare the late effects of aureomycin and terramycin with any accuracy. Daily sigmoidoscopy showed a rate of healing and a rate of disappearance of ulcers which appeared to differ in no way from the results with aureomycin. 8 cases (16·3%) were healed by the fourth day and 32 (65·0%) by the seventh day. By the fourth day 77·6%, and by the seventh day 89·7%, had been cleared of amœbæ. Giant forms of amœba were not seen during treatment with terramycin.

TABLE VIII—RESULTS WITH CHLORAMPHENICOL 4 G. DAILY FOR THREE DAYS FOLLOWED BY 2 G. DAILY FOR NINE DAYS (TOTAL 30 G.)

Assessment	No. of cases (total 16)		
	At 10 days	At 20 days	At 27 days
Successes	13 (*81·3%*)	12 (*75·0%*)	10 (*62·5%*)
Probable failures	2 (*12·5%*)	Nil	Nil
Cyst-passers	1 (*6·2%*)	3 (*18·8%*)	3 (*18·8%*)
Absolute failures	Nil	1 (*6·2%*)	2 (*12·5%*)
Removed from treatment	Nil	Nil	1 (*6·2%*)
Combined failure-rate	6·2%	25·0%	37·5%

Chloramphenicol

The results of treating 16 patients with chloramphenicol 4 g. daily for three days, followed by 2 g. daily for nine days, are shown in table VIII. Initially, these patients progressed well. All were free from amœbæ by the fifth day, and 14 were healed on the tenth and fifteenth days. However, both parasitic and symptomatic relapses were frequent and early. There were 3 absolute failures: 1 on the twentieth, 1 on the twenty-fifth, and 1 on the twenty-sixth day after treatment had started.

TABLE IX—RESULTS WITH NEOMYCIN 40,000 UNITS INITIALLY FOLLOWED BY 10,000 UNITS FOUR-HOURLY FOR TEN DAYS (TOTAL 540,000 UNITS)

Assessment	No. of cases (total 12)		
	At 10 days	At 20 days	At 27 days
Successes	5 (*41·7%*)	5 (*41·7%*)	4 (*33·3%*)
Probable failures	2 (*16·7%*)	Nil	Nil
Cyst-passers	Nil	Nil	Nil
Absolute failures	4 (*33·3%*)	Nil	1 (*8·3%*)
Removed from treatment	1 (*8·3%*)	7 (*58·3%*)	7 (*58·3%*)
Combined failure-rate	41·6%	58·3%	66·6%

Of 15 successes at twenty days and 13 successes at twenty-eight days, 3 were passing cysts. At the end of eight months a further 4 successful cases had a full relapse with ulcers and trophozoites in the stools. At the outset healing of ulcers and disappearance of amœbæ were as rapid and dramatic as with aureomycin and terramycin, but we noticed that some inflammation often remained in the bowel. As with streptomycin, there were tendencies to form cysts and towards symptomatic relapse.

TABLE X—RESULTS WITH BACITRACIN 40,000 UNITS INITIALLY FOLLOWED BY 10,000 UNITS FOUR-HOURLY FOR TEN DAYS (TOTAL 540,000 UNITS)

Assessment	No. of cases (total 12)		
	At 10 days	At 20 days	At 27 days
Successes	10 (*83·3%*)	9 (*75·0%*)	8 (*66·6%*)
Probable failures	Nil	Nil	1 (*8·3%*)
Cyst-passers	Nil	Nil	Nil
Absolute failures	1 (*8·3%*)	Nil	Nil
Removed from treatment	1 (*8·3%*)	3 (*25·0%*)	3 (*25·0%*)
Combined failure-rate	16·6%	25·0%	25·0%

Neomycin

Of the 12 patients to whom we gave neomycin 40,000 units initially, followed by 10,000 units four-hourly for ten days, no less than 7 had to be removed from treatment owing to deterioration of their condition, and it will also be seen (table IX) that 1 case classed as a "success" at twenty days had reverted to an absolute failure at twenty-seven days.

Bacitracin

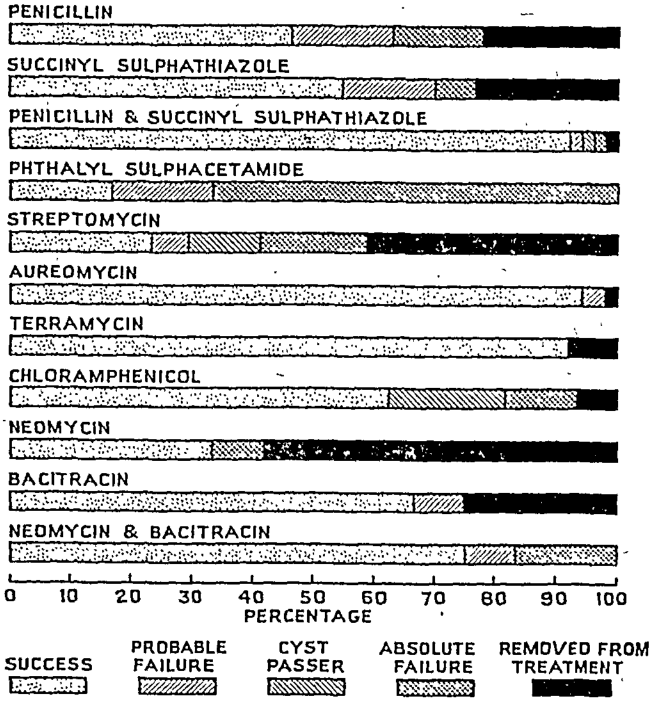
Bacitracin 40,000 units initially, followed by 10,000 units four-hourly for ten days, was given to 12 patients. It will be seen (table X) that some of the patients initially classed as successes were given other treatment before their period of observation was complete, because of deterioration in their clinical condition and/or reappearance of ulcers or parasites.

TABLE XI—RESULTS WITH BACITRACIN AND NEOMYCIN 20,000 UNITS OF EACH INITIALLY, FOLLOWED BY 5000 UNITS OF EACH FOUR-HOURLY FOR TEN DAYS (TOTAL 270,000 UNITS OF EACH)

Assessment	No. of cases (total 12)		
	At 10 days	At 20 days	At 27 days
Successes	10 (*83·3%*)	11 (*91·7%*)	9 (*75·0%*)
Probable failures	2 (*16·7%*)	Nil	1 (*8·3%*)
Cyst-passers	Nil	1 (*8·3%*)	Nil
Absolute failures	Nil	Nil	2 (*16·7%*)
Combined failure-rate	Nil	8·3%	16·7%

Bacitracin and Neomycin

The results of treating 12 patients with bacitracin and neomycin 20,000 units of each initially, followed by 5000 units of each four-hourly for ten days, are shown in table XI. No case deteriorated sufficiently to warrant removal from the series. Indeed in all 12 cases healing of ulcers was complete by the twentieth day, and all were classed as successes. One of these patients, however, was passing cysts, but still had no ulcers on the twenty-seventh day. 1 successful case discharged himself on the twentieth day and is considered to have been a success



Results of treatment of amœbic dysentery with antibiotics.

at twenty-seven days. 2 absolute and 1 probable failures were found at twenty-seven days; all 3 had reverted from successes at twenty days.

DISCUSSION

From the foregoing results, which are illustrated in the accompanying figure, it will be seen that certain of the antibiotic drugs can produce an immediate apparent cure in a very high proportion of cases of the acute ulcerative amœbiasis which we encounter here in Durban. Apparently we can profoundly modify the course of the disease by an attack on the bacterial flora associated with the parasite. The disappearance of the parasite in these circumstances suggests that the bacterial flora in some way supports the amœba. Not all antibiotics operate in the same way. For example, the use of penicillin left some 30% of cases with amœbæ, and the same may be said of succinyl sulphathiazole. However, in combination these two drugs left only 3 out of the 50 cases harbouring parasites—a degree of success attained also by aureomycin and terramycin. In comparison with succinyl sulphathiazole the other sulphonamide tried, phthalylsulphacetamide, had relatively little effect. Streptomycin only cleared some 30% of cases of their amœbæ, as did neomycin. Bacitracin and chloramphenicol each cleared some 80%, and there was, if anything, a slight improvement on this figure by the combination of neomycin and bacitracin.

In deciding which is the most effective agent it is wise to watch the progress of the figures as well as the actual figures themselves. If the combined failure-rate is watched for each drug at ten, twenty, and twenty-seven days, it will be seen that there is a decline in the case of both penicillin and succinyl sulphathiazole; an insignificant change or no change in the highly effective drugs aureomycin, terramycin, and combined penicillin and succinyl sulphathiazole; and a steady and significant increase in the numbers of failures with the relatively unsuccessful drugs streptomycin, chloramphenicol, neomycin, bacitracin, and combined bacitracin and neomycin. From this we conclude that the most effective agents in this respect are aureomycin, terramycin, and penicillin and succinyl sulphathiazole used in combination.

It is apparent from these facts that the wider the range of bacteria attacked the higher is the proportion of successes in any given series. It seems from this that a wide variety of organisms can support the amœbæ in the bowel.

In the present cases the establishment of a cyst-passing phase was a rarity; yet under the action of streptomycin and chloramphenicol many of these cases were converted from the acute trophozoite-passing phase to that of the symptomless cyst-passer. Attempts to duplicate this in vitro were unsuccessful.

Although aureomycin given by mouth did not produce cyst-passers, both the patients treated with this drug intravenously passed through a cyst-passing phase before relapsing. Possibly this was due to the short duration of treatment.

So far we have been discussing the effect of the antibiotics as if this effect was only through the associated bacterial flora, but there is more than a little evidence that certain of the antibiotics may have a directly *amœbicidal* effect.

The assessment of such an effect is most difficult in vitro because *E. histolytica* will not grow alone. To assess how much of an antibiotic's effect has been on the amœba itself and how much on the associated bacteria is practically impossible. However, by exposing amœbæ to various agents, washing them, and replacing them in their original flora, it is possible to form some idea about whether a particular antibiotic has a direct effect. In our hands, as in those of other workers (Hewitt et al. 1950), aureomycin and terramycin are amœbicidal in concentrations likely to be reached in the bowel.

We have shown (Wilmot et al. 1952) that aureomycin has little or no effect on amœbic liver abscess, where there is no confusion between antibacterial and antiamœbic effect. This suggests that the action of aureomycin in bowel cases is mainly on the symbiotic bacteria.

A further feature of the antibiotic treatment of amœbiasis is the rapidity with which the lesions heal and the amœbæ disappear. Under aureomycin therapy, on the tenth day 67% of cases had been cleared of their ulcers, and 98% of their amœbæ. Under terramycin 84% had been cleared of their ulcers, and 94% of their amœbæ. It will be seen that there is little difference between aureomycin and terramycin in this respect.

One of the criticisms of antibiotic therapy made by most workers is that there is a high relapse-rate. As mentioned before, we are unable, from the nature of the cases on which we are working, to give any accurate estimates of the relapse-rates under different varieties

TABLE XII—FOLLOW-UP RESULTS

—		Penicillin and succinyl sulphathiazole	Aureomycin	Terramycin	Strepto-mycin	Bacitracin	Bacitracin and neomycin
No. treated		54	52	49	17	12	12
No. discharged as cured		46	48	42	6	8	8

	Success ..	..	..	..	..	..	..
	Failure ..	..	..	1	..	..	..

of therapy—not only do the patients not return until they are ill, but also one has to bear in mind that the Bantu in Durban is not only extremely susceptible but is also, from the nature of his home surroundings, very heavily exposed to a new infection. Nevertheless there can be little doubt that relapses take place after antibiotic treatment. Table XII gives some indication of the relapses as seen. All that can be said from this table is that relapses occur after antibiotic treatment as indeed they do after any other form of therapy. We have no evidence that they are more frequent.

It therefore seems that, though the antibiotics can clear the clinical condition in severe dysentery and remove amœbæ from most of them, it is advisable to use some direct amœbicide in addition.

SUMMARY

Certain antibiotic drugs are very effective when used alone in the treatment of acute amœbic dysentery. Not only do ulcers and symptoms clear up, but also in many cases the amœbæ disappear. In this respect aureomycin, terramycin, and a combination of penicillin and succinyl sulphathiazole are the most effective. Treatment with them produces a much higher immediate cure-rate than can be obtained with any single directly amœbicidal drug (see Wilmot et al. 1951).

Probably the main action of the antibiotics is on organisms other than the amœba. Whether these organisms assist the amœba by attacking the host or by the supply of essential factors remains in doubt. There is in-vitro evidence that aureomycin and terramycin have some direct anti-amœbic effect.

To ensure success it seems that the antibiotics used should have the widest possible antibacterial "spectrum," for it is known that more than one species of bacterium can support the amœba, and all possible symbionts should be removed.

Under the action of certain antibiotics, notably chloramphenicol and streptomycin, acute dysenteric cases may be converted to symptomless cyst passing. It seems that an inadequate antibiotic or inadequate dosage will curb invasiveness and promote cyst passing.

With aureomycin and terramycin early relapses after four to eight weeks are fairly usual. With the other antibiotics relapses are common. We therefore feel that established amœbicides should at present be used in conjunction with antibiotics.

Work of this nature could not be carried out without the coöperation of the manufacturers and it is with the greatest of pleasure that we record our thanks to the Schering Corporation, Bloomfield, N.J., for the supply of phthalylsulphacetamide and streptomycin; Lederle Laboratories, New York, for the supply of the very large quantities of aureomycin we have used; Chas. Pfizer & Co. Inc., Brooklyn, N.Y., for the very generous supply of terramycin; Parke, Davis & Co., Detroit, Mich., for large supplies of chloramphenicol; and Commercial Solvents, Terre Haute, Indiana, for the supply of neomycin and bacitracin. Not only have these companies been most generous in making the material available, but they have also been of the greatest assistance with the supply of literature and advice.

A METHOD OF ASSESSING THE MECHANICAL PROPERTIES OF LUNGS AND AIR-PASSAGES

A. C. DORNHORST
M.D. Lond., M.R.C.P.
READER IN MEDICINE

G. L. LEATHART
M.B. Camb., M.R.C.P.
LECTURER IN MEDICINE

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL, LONDON

THIS paper describes a method of estimating the force needed to ventilate the lungs. When this force is increased, the method helps to define its cause; it also provides an objective test for bronchodilator drugs.

METHOD

Principle

The respiratory muscles have to overcome two types of force: elastic force due to the stretching of the lungs and therefore depending on the depth of inspiration; and viscous force due mainly to the resistance offered by the air-passages to the flow of air and therefore depending on the rate of air movement.

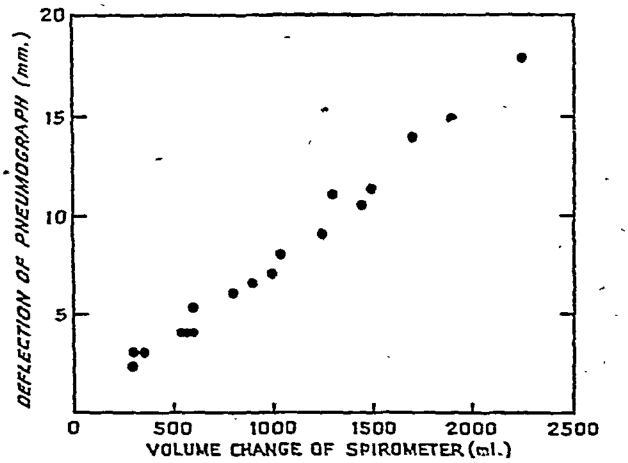

Fig. 1—The approximate linear relationship between expansion of trunk and tidal air measured with a spirometer.

Fibrosis renders the lungs less distensible and increases the first type of force: bronchiolar narrowing, or other impediment to airflow, increases the second. Simultaneous records of the total force applied to the lungs and of the resulting movement allow an assessment of the contributions of the elastic and viscous components. The total force is proportional to the pressure round the lungs—i.e., the intrathoracic pressure. To estimate this we have measured the pressure in the œsophagus. Lung

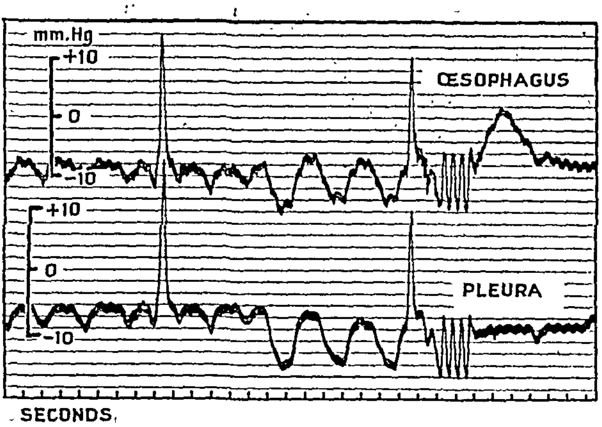

Fig. 2—Dynamic agreement of œsophageal and pleural pressures in a case of spontaneous pneumothorax. The spikes are due to small coughs. At the right of the tracing the œsophageal pressure rises in a characteristic way due to a swallow. Time is marked in seconds.

expansion has been estimated from records of increase in the girth of the chest and abdomen.

Procedure

A 'Polythene' tube of about 1 mm. external and 0·5 mm. internal diameter is prepared by cutting two or three lateral holes near one end. This end is passed through the nose into the œsophagus. The free end is attached to a capacitance manometer, and the system is filled with water. The fine plastic tube disturbs the patient less than does a tube of the Ryle type.

To record trunk expansion a length of "elephant" tubing is lightly strapped round the chest and another round the abdomen. The two lengths are joined by a Y connection to a second manometer, which records the decrease in pressure produced by stretching the tubing. The output of this manometer may be passed through a circuit that gives the rate of change of expansion as an additional record.

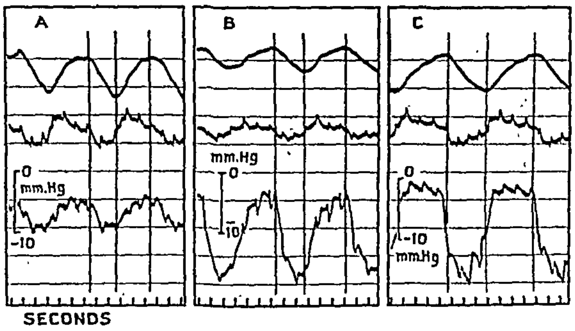

Fig. 3—Pneumograph, pneumotachygraph, and œsophageal pressure from a normal person: A, unimpeded breathing; B, breathing from a closed tank, simulating increased elastic forces; C, breathing through a narrow tube, simulating increased viscous forces. Note different form and timing of enhanced intrathoracic pressure swing in the last two sections.

Validation

Fig. 1 shows that the deflection produced by the pneumograph agrees well with the amount of air inspired.

When a person blows (or sucks) against a mercury column, the applied pressure is found to be transmitted to the œsophagus and fully maintained there. Fig. 2 shows that changes in intrapleural pressure are duplicated in the œsophageal.

ILLUSTRATIVE RESULTS

Fig. 3 is from the record of a normal person and shows the differing effects of factitious increases in elastic and viscous forces.

Fig. 4 illustrates the corresponding patterns in pathological states.

Fig. 5 illustrates an unequivocal bronchodilator response to a drug.

DISCUSSION

The method here described relates the pressure applied to the lungs to their consequent movement, and thus defines their mechanical impedance. An increase in this is one factor in the production of dyspnœa. When it is increased, it is of interest whether the viscous or the elastic component is chiefly responsible. An inspection of the records will usually answer this question; or, if necessary, the magnitude of the components may be estimated by a method due to von Neergaard and Wirz (1927). The analysis depends on the fact that at the end of an inspiration, when there is no air movement, the recorded pressure is due to elastic forces only. By comparing a series of respirations of differing depth it is possible to construct an elastic (depth-pressure) characteristic for the subject. One may then subtract from the observed pressure at any point of a respiratory cycle that part due to lung stretch. What remains must be due to viscous forces and is related to the rate of airflow at that moment. The viscous characteristic may thus be constructed.

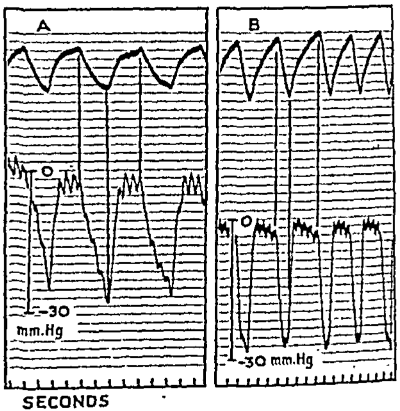

Fig. 4—Pneumograph and intra-œsophageal pressure: A, from a case of pulmonary fibrosis, illustrating increased elastic forces (cf. fig. 3B); B, from a case of severe asthma, illustrating increased viscous forces (cf. fig. 3C).

Previous workers have measured the intrapleural pressure in patients with pneumothorax, but this technique is not generally applicable. We are satisfied that the intra-œsophageal pressure, which can be measured in any patient with very little disturbance, is an adequate substitute.

We have measured trunk expansion, rather than air movement, for greater comfort to the patient and for greater ease of recording. We consider this, and the "pneumotachygraph" obtained by electrical differentiation, adequate for visual analysis, but for the quanti-

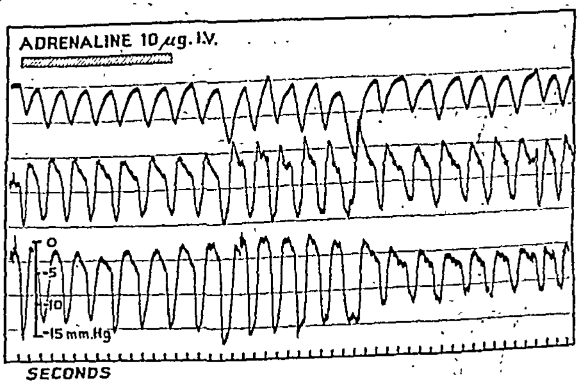

Fig. 5—Pneumograph, pneumotachygraph, and intra-œsophageal pressure in moderate asthma, showing effect of adrenaline. After brief stimulation of respiration adrenaline dilates bronchioles and decreases intrathoracic pressure swing.

tative treatment outlined above a direct record of airflow would be preferred.

When applying the method to the assessment of bronchodilator drugs one selects from the record, before and after treatment, respiratory cycles which agree in their volume patterns. One thus eliminates any action of the drug on respiratory drive; any change in the pressure pattern may then be attributed to an effect on the bronchioles.

SUMMARY

The pressure in the œsophagus is readily measured, and is a satisfactory index of the general intrathoracic pressure.

By simultaneous measurement of œsophageal pressure and trunk expansion it is possible to estimate and analyse the force needed to expand the lungs.

Some applications are described and illustrated.

During the past two years several workers (Gordon et al. 1951, Renold et al. 1951, McIntosh and Holmes 1951, Mandel et al. 1951) have advocated the intravenous route as the most effective and economical way of giving adrenocorticotropic hormone (A.C.T.H.). Though isolated incidents of reactions have been reported (Mandel et al. 1951, Wilson 1951), the opinion from major centres where this technique has been widely used is that such incidents are exceedingly rare. McIntosh and Holmes (1951) gave various doses of intravenous A.C.T.H. over 24-hour periods to two patients, and suggested that there is a minimum dose which will produce a maximum or nearly maximum stimulation of the adrenal cortex.

The present study extends these observations and relates the dose of continuously administered intravenous A.C.T.H. to the rate of the eosinopenic response.

METHODS

A.C.T.H. (Armour L-A 1-A)* was given to five patients by intravenous drip, the diluent used in all cases being 5% dextrose water. Each patient was given a series of such infusions, the quantity of A.C.T.H. differing in each. The amount of diluent used was 800 or 1000 ml., and in all cases the material was given over 8 hours. The total amount of A.C.T.H. given varied from 0·4 to 20 mg., and this dose was expressed in mg. per hour, thus varying from 0·05 to 2·5 mg. per hour.

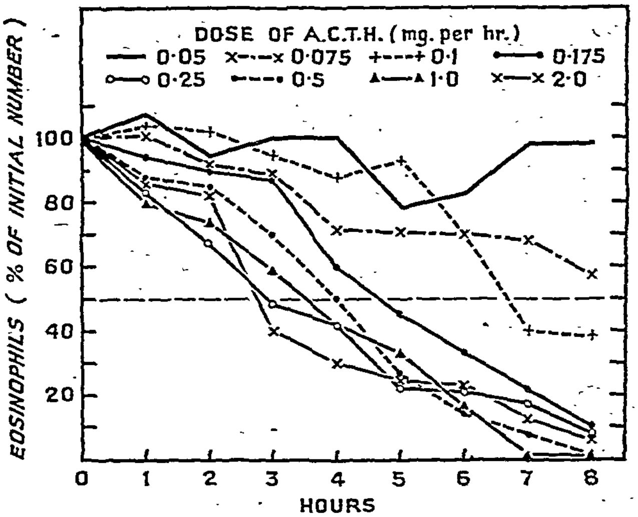

Fig. 1—Eosinopenic response in case 1.

During each infusion eosinophil-counts were made at short intervals, hourly in most cases. The counts were done by Thorn's modification of Dunger's method.

The observations were made at intervals of 3–5 days to exclude the possible occurrence of progressive adreno-cortical hyperplasia.

RESULTS

Fig. 1 shows the results obtained in case 1. It will be seen that the graphs fall into three main groups. Group I representing 0·05 mg. per hour, shows no progressive fall in the number of eosinophils. Group III is that in which a fall of 50% or more in eosinophils has occurred within 4 hours: it includes all doses of 0·25 mg. per hour or greater. Group II, with a range of dosage from 0·075 to 0·175 mg. per hour, lies in an intermediate position between the other two, with an apparently progressive increase in rate and degree of fall of the eosinophils.

Case 2 (fig. 2) shows a very similar picture. It will be seen that, though the intermediate group lies in the same dose range, the rate and amount of fall are greater than in case 1. A further point clearly illustrated by case 2 is that, once a fully effective dose is given, further

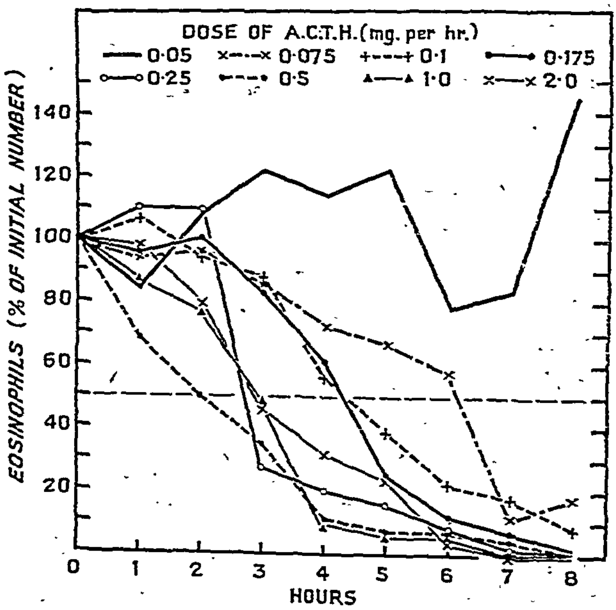

Fig. 2—Eosinopenic response in case 2.

---

* Lot nos. K 30002 and J 26311

increases do not affect the rate and amount of fall; for example, in this case 0·25 mg. per hour appears to produce a more rapid fall than 2 mg. per hour. These minor differences are not considered significant but may be explained by inaccuracies inherent in counting eosinophils.

Similar results were obtained in three other cases. When 5% dextrose water alone was given, there was no eosinopenic response. In case 4 two infusions were given with the same amount of A.C.T.H. (0·25 mg. per hour), and the results showed that the graphs were reproducible at different times in the same patient. The minimum *dose that is fully effective varied in the different patients*, case 5 showing a full response to 0·12 mg. per hour, whereas cases 1 and 2 required 0·25 mg. per hour.

From these observations it is clear that the minimum effective dose of intravenous A.C.T.H. which produced a maximum fall in number of circulating eosinophils in the minimum time lay between 0·1 and 0·25 mg. per hour in the five patients studied. Though the minimum effective doses found in these five cases were all of the same order, there were minor variations, and it is likely that each individual has his own critical level at which a full eosinopenic response occurs. It is noteworthy that the difference between a non-effective dose and a fully effective one is very small. This fact was emphasised in an accidental finding during two infusions given to two patients. In these two infusions the intended dose was 0·1 mg. per hour. However, after about 4 hours it was noted that less than half the infusion had been given, and in an attempt to adjust this the rate of flow was increased. Though no effect on the eosinophils had been observed during the first period before alteration of the rate of flow, in the second period a partial response took *place in each case.*

DISCUSSION

Gordon et al. (1951), using relatively large amounts of A.C.T.H. intravenously, demonstrated an enormous increase in adrenal cortical activity. Renold et al. (1951) showed that considerably smaller doses were equally effective, a full eosinopenic response being obtained with 20 mg. given intravenously in 48 hours, or at a dose of rather less than 0·5 mg. per hour. McIntosh and Holmes *(1951) obtained* a full eosinopenic response with 5 mg. given in 24 hours on an hourly dose of just over 0·2 mg. Mandel et *al.* (1951) found a similar dose to be effective. Our studies go further and establish clearly the minimum rate of intravenous A.C.T.H. dosage required to produce a full eosinopenic response. This rate varies from *0·1 to* 0·25 mg. per hour in the cases observed. As a corollary to this it seems logical to suggest that the amount of A.C.T.H. produced by the pituitary in response to stress, over and above the normal rate of secretion, must be at least 0·10–0·25 mg. per hour.

Swanson (1951) and Renold et al. (1951) have reported anomalous results with the intramuscular Thorn test. In a small but significant number of persons A.C.T.H. appears to be inhibited or destroyed locally at the site of the injection, and false results are obtained. Data *suggesting such an effect are being reported by one of us* (H. W. M.) confirming earlier experience (Mandel et al. 1951). It therefore seems reasonable to suggest that this test is most satisfactorily made by giving the hormone in an 8-hour intravenous drip as proposed by Renold *et* al. (1951). We feel, also, that there is an advantage in making at least two eosinophil-counts between the sixth and eighth hours to eliminate errors due to technique, and to safeguard against false results produced by the diurnal variations in eosinophil levels suggested by Rud (1947) and recently confirmed by Swanson et al. (1952). Our present results indicate that as little as 2 mg. of A.C.T.H. would be sufficient for such a test in most cases, although we advise 5 mg. for a routine test.

Case no.	Age (yr.)	Weight (lb.)	Disorder	Previous history of allergy	Minimal effective eosinopenic dose of A.C.T.H. (mg. per hr.)
1	51	170	Rheumatoid arthritis	No	0·25
2	35	80	Rheumatoid arthritis	No	0·25
3	34	142	Alopecia universalis	Yes	0·25
4	48	164	Alopecia universalis	Yes	0·10
5	42	205	Rheumatoid arthritis	No	0·12

Our small group of patients demonstrate minor variations in the minimum effective eosinopenic dose o A.C.T.H. In the accompanying table have been listed few salient points about the five patients, includin weight, age, disorder present, history of allergy, an minimum effective dose of A.C.T.H. No relations betwee these factors and the minimum effective dose of A.C.T.I are apparent.

Our observations reopen a further question. Is th eosinopenic *response merely a sensitive indicator* increased adrenal cortical secretion, or does it represen a full stimulation of the adrenal cortex over any fixe period of time? To answer this question a correlatio between data of this type and measurements of oth adrenocortical activities might give useful informatio Such studies are now in progress and will be reported.

SUMMARY AND CONCLUSION

Various amounts of A.C.T.H. were given intravenousl over an 8-hour period to five patients, and it was foun *that 0·10–0·25 mg. per hour was required to produce* maximum eosinopenic response.

The administration of quantities ten times this amou was no more effective and produced the same type response.

There is a minimum rate of intravenous administratio *of* A.C.T.H. which produces a maximum eosinope response. The implications of this finding with regard therapy and testing adrenocortical function are discusse

These observations were made in the course of projec supported by the National Research Council of Canada. T Fellowship in Clinical Investigation is supported by t Medical Board of the Vancouver General Hospital.

NUTRITIONAL NEUROPATHY IN PRISONERS-OF-WAR REPATRIATED FROM HONG-KONG

A FOLLOW-UP

C. A. Clarke
M.D. Camb., F.R.C.P.
ASSISTANT PHYSICIAN, UNITED LIVERPOOL HOSPITALS (DAVID LEWIS NORTHERN BRANCH); VISITING PHYSICIAN, BROADGREEN HOSPITAL, LIVERPOOL

W. Sircus
M.D. Lpool, M.R.C.P.
LECTURER IN PHYSIOLOGY IN THE UNIVERSITY OF LIVERPOOL; LATE SENIOR MEDICAL REGISTRAR, BROADGREEN HOSPITAL, LIVERPOOL

This is a follow-up of patients with nutritional neuropathy seen by one of us (C. A. C.) at the Royal Naval Hospital, Sydney, Australia, in 1945. At that time 200 recently released prisoners-of-war came into our hands, and 74 of them showed grossly abnormal neurological signs referable to their malnutrition. The principal features were optic atrophy with scotomata, ataxia, and sometimes deafness (Clarke and Sneddon 1946). The syndrome was described by other workers, and the whole subject comprehensively reviewed by Spillane (1947) and by Smith and Woodruff (1951).

The follow-up was designed to find out whether the condition of these seriously disabled patients had remained stationary, become worse, or improved; 53 case-histories were traced, and detailed letters of inquiry were sent. There were 34 replies, but in 5 of them the evidence was insufficient to make an accurate assessment and they are therefore excluded from the series. Later, 8 of the remaining 29 patients were personally examined by us at the David Lewis Northern Hospital, Liverpool. The following extracts from the letters vividly illustrate the residual disabilities:

> "Should say no alteration in eyes either way since leaving Sydney. . . . I am not able to recognise faces even at four or five paces in ordinary light. . . . The weakness of the legs has not disappeared, but there has been a considerable improvement. Numbness and tingling of the legs are still very much in evidence. . . ."

> "My sight is the same as in 1945. I cannot read a newspaper with or without glasses. . . . My legs have improved to some extent . . . balance still a little unsure when walking slowly. . . ."

> "I do not seem to have control over my toes. . . . My balance has improved a little—although when washing my face with eyes closed it is not so good, but I have full confidence standing in the bath with my eyes open. My eyes seem a little better some days. I can read the headlines of a paper, but I must confess I would be lost without my high-power reading-glass, which has three lenses. It helps me a lot. I hold it about 1 in. from my eyes and 2 in. from the paper. I am a 'borderline' case of St. Dunstan's."

> "My sight is certainly no worse and, I think, slightly better than in 1945. With the aid of a special pair of binocular spectacles with magnifying lens I can read twelve pages of a decently printed book in an hour."

> "The deafness has improved compared to what it was. It is still pretty bad. . . . I have been given a hearing-aid, but it is not much use, and if people are talking to each other I can hear voices but not pick out the words."

> "The eyes have not improved, and now I'm registered as blind. The hands are much better and seem normal except that the finger-tips sometimes lose feeling and the ability to read Braille. . . . You will realise by the above that my correspondence was written by another."

> "My eyes are still in the same condition as in Australia. They haven't got any worse or any better. I am unable to read or play in sports or enjoy pictures, but I can see to get about. I have a steady job on the council road-sweeping. I get a pension of a hundred per cent. for my eyes."

> "As for the pinprick, I think it is about the same. In some places it is sharp and in others it is blunt. . . . I still do not know where my feet are unless I see them, but if the bottoms of my feet are touched I jump a mile."

ANALYSIS OF FOLLOW-UP

Visual Disturbances

Of the 29 patients 26 had some disturbance of visual acuity in 1945. In 15 of these we assessed it as severe and in 11 as mild. In 1951 14 of the severe cases remained unchanged and 1 was slightly worse. In the mild group 6 were unchanged, 2 had fully recovered, 1 had improved, and 2 had deteriorated. The assessment was made on the patients' statements in about half the cases, and in the remainder from the Ministry of Pensions records or our own examination.

Where objective records were available, examination showed that in 13 patients who had had scotomata in 1945, whether severe (9) or mild (4), there was no change in 1951. Similarly there was no change in the 9 cases with optic atrophy of which we had records. Of the cases showing macular degeneration, only 2 objective examination reports in 1951 were available, and both of these showed no change since 1945.

Deafness

There were 10 cases in this group; 6 severe and 4 mild. In 5 of the severe group there was no change in 1951, and 1 patient said that he had deteriorated; 2 of the mild cases had recovered (1 by 1945), and 2 had improved.

Posterior-column Lesion

18 patients had been affected in 1945; 7 severely and 11 mildly. In 1951 4 of the severe group were unchanged, 1 was worse, and 2 had improved. In the mild group 4 had completely recovered, 4 had improved, and 3 were unchanged.

Peripheral-nerve Lesion

In 1945 18 cases showed evidence of peripheral neuropathy (analgesia, anæsthesia, and diminished tendon-reflexes): 12 were assessed as mild and 6 severe. 7 of the mild cases had improved, and 5 had completely recovered by 1951. 4 of the severe cases were unchanged, 1 had improved, and 1 had recovered. In 4 patients knee and ankle reflexes, which had been absent in 1945, had returned by 1951.

Hyperæsthesia of Soles

In 4 patients this had been severe in 1945. Six years later the condition was unchanged in 2, and 2 had recovered.

"Electric Feet"

This symptom was still present in 1951 in 4 of the 5 cases where it had been a pronounced feature earlier; 1 patient had recovered.

Foot-drop

There were 4 cases of bilateral foot-drop in 1945, and after six years 2 were unchanged and 2 had somewhat improved.

Lateral-column Lesion

1 patient had been seen in 1945 in whom the signs resembled amyotrophic lateral sclerosis. In 1951 his condition had changed very little, and the case is reported in detail below (case 5).

Miscellaneous

1 typical case of dystrophia myotonica was found in the follow-up. The patient had deteriorated slightly in the six years (see case 6 below). In 1945 his condition

had been diagnosed as beriberi, but the correct diagnosis had been made earlier when he was in the prison camp.

ILLUSTRATIVE CASE-RECORDS

Case 1.—Now aged 30, he was taken prisoner on Christmas Day, 1941.

April, 1942.—Dysentery followed by chronic diarrhœa off and on for four months.

May, 1942.—Sore tongue, angular stomatitis, and numbness of feet and hands.

August, 1942.—Blurred vision with gradual development of blind spot.

October, 1942.—Supplies of eggs and milk and nicotinic acid became available, and weakness and numbness of the extremities improved. Eyes improved slightly to January, 1943; static since.

1945.—Visual acuity rt. and lt. 2/60 only. Large absolute central scotomata and optic atrophy; no macular changes. Ankle reflexes absent; knee reflexes diminished. Vibration sense absent at ankles; positive rombergism. Sense to pinprick defective on outer side of legs.

1951.—Visual acuity for hand movements only. Scotomata and optic atrophy all unchanged. Unable to read a newspaper. Tendon reflexes now normal. Diminished vibration sense and sense of position in both legs. Deep sensation absent. Slight rombergism, but has improved. Touch and sense to pinprick, heat, and cold all normal.

Summary.—Main disability now defective eyesight. He can work as a full-time physiotherapist.

Case 2.—Now aged 58, he was taken prisoner on Christmas Day, 1941.

May, 1942.—Œdema of the ankles.

September, 1942.—Deterioration of vision with blind spots.

May, 1943.—Scrotal dermatitis.

March, 1944.—Numbness of legs and ataxia.

August, 1944.—Foot-drop.

1945.—Visual acuity rt. (corr.) 6/9, lt. (corr.) 6/7·5. Very small relative scotoma present in right eye. Temporal pallor of discs. Leg reflexes absent. Vibration sense in legs absent. Rombergism and glove-and-stocking anæsthesia present.

1951.—Eyes unchanged. Absent leg reflexes. Gross posterior-column loss with rombergism. Glove-and-stocking anæsthesia as in 1945. Hyperæsthesia of soles.

Summary.—Well-marked persistence of posterior-column and peripheral-nerve changes. Eyes subjectively improved between 1941 and 1945.

Case 3.—Now aged 39, he was taken prisoner on Christmas Day, 1941.

May, 1942.—Slight deafness developed.

November, 1942.—Amblyopia.

December, 1942.—Ataxia.

February, 1943.—Numbness of the feet.

1945.—Visual acuity, rt. 6/60, lt. 6/60 (uncorrectable). Bilateral absolute central scotomata. Discs pale. Hearing now normal. Absent leg reflexes. Posterior-column loss in legs. Anæsthesia of legs. Hyperæsthesia of feet.

1951.—Visual acuity unchanged. Scotomata and discs unchanged. Leg reflexes present but diminished. Very slight posterior-column loss in legs. Very slight loss of pain sensibility in legs.

Summary.—Vision unchanged. Great improvement in legs.

Case 4.—Now aged 49, he was taken prisoner on Christmas Day, 1941.

May, 1942.—Dysentery.

July, 1942.—"Electric feet."

December, 1942.—Severe mental depression. Visual symptoms with central scotomata. Ankle reflexes absent: knee-jerks brisk. Numbness of legs, with anæsthesia of the shins and hyperæsthesia of the feet.

1945.—Depression unchanged. Visual acuity rt. 6/60, lt. 4/60. Absolute central scotomata (bilateral). Pigmented maculæ. Absent leg reflexes. Severe posterior-column loss. Rombergism present. Anæsthesia of shins unchanged.

1951.—Still depressed. Eyes unchanged. Macular atrophy persists. Left ankle reflex absent, otherwise leg reflexes normal. Posterior-column loss, rombergism, anæsthesia of shins, and hyperæsthesia of feet all unchanged.

Summary.—Persistent optic and macular atrophy. Gross persistent posterior-column changes.

Case 5.—Now aged 30, he was taken prisoner on Christmas Day, 1941.

April, 1942.—Failing vision.

August, 1942.—Dysentery.

December, 1943.—Scotomata noted. Absent corneal reflexes. Moderate deafness. Ataxia with bilateral foot-drop. Numbness of legs. Soreness of tongue and mouth.

1945.—Pallor of optic discs. Macular pigmentation. Visual acuity rt. 6/36, lt. 6/36. Small paracentral scotomata. Much left facial weakness (lower-motor-neurone type). Lateral nystagmus present. Limbs showed typical amyotrophic lateral sclerosis syndrome with wasting small muscles of hand and increased reflexes and spasticity in legs. Foot-drop present. Severe posterior-column loss. Micturition precipitate. Cerebrospinal fluid normal.

1951.—Visual acuity, scotomata, and macular pigmentation all unchanged. Hearing much better. Facial paresis persists. Nystagmus unchanged. Legs less spastic, but reflexes increased. Plantar responses invalid owing to complete (unchanged) foot-drop. Posterior-column loss in legs unchanged.

Summary.—Amyotrophic lateral sclerosis syndrome of nutritional origin. No regression. Slight improvement in gait.

Case 6.—Now aged 44, he was taken prisoner on Christmas day, 1941.

September, 1942.—Dysentery.

October, 1942.—Weakness of legs. Numbness of hands. No eye symptoms.

November, 1942.—Scrotal eczema. Much weakness of arms and legs. All tendon reflexes absent. Vibration sense absent in legs. Severe myotonia noted and myotonia atrophica diagnosed.

April, 1943.—Foot-drop reported.

1945.—True diagnosis missed, and findings in central nervous system thought to be result of malnutrition.

1951.—Classical dystrophia myotonica facies and typical findings in central nervous system. Slight testicular atrophy. Glossal myotonia. Congenital dot opacities of lenses. Severe foot-drop. Some posterior-column loss in legs. Family history gives no definite lead.

Summary.—Dystrophia myotonica possibly precipitated by malnutrition.

SUMMARY AND CONCLUSIONS

29 cases of severe nutritional neuropathy have been followed up after an interval of six years, and the various features of the condition assessed.

The visual signs (visual acuity, scotomata, and optic atrophy) have persisted largely unchanged irrespective of the degree of involvement.

The auditory nerve seems to have been less vulnerable in that some recovery took place in all the mild cases.

Severe posterior-column loss has remained unaltered, but, where it was slight, some improvement has taken place.

The most obvious improvement in the series was in patients with peripheral-nerve lesions.

The one case resembling amyotrophic lateral sclerosis has remained unchanged.

We acknowledge with thanks the great help given to us by the Medical Director-General of the Royal Navy in supplying us with the old case-sheets and for permission to publish. We are also grateful to Dr. F. T. Rees, C.B.E., M.C., T.D., for giving us access to the Ministry of Pensions records; to Mr. McKie Reid, M.C., T.D., and his staff for the scotoma records, and to the board of governors, United Liverpool Hospitals, for defraying the expenses of the follow-up.

MEDICAL REGISTRAR

ROYAL HOSPITAL, SHEFFIELD

THE increasing use of A.C.T.H. and cortisone has ttracted attention to the potential dangers of these ormones in the presence of known or unsuspected uberculosis (*British Medical Journal* 1951). The rôle of hese agents in the treatment of the collagen diseases as now been extensively investigated. It appears that hey have a limited value in the therapy of disseminated upus erythematosus (Soffer et al. 1950). The possible elation between tuberculosis and disseminated lupus rythematosus remains, for the present, controversial Keil 1933).

This case of disseminated lupus erythematosus compliated by miliary tuberculosis during cortisone therapy s therefore thought worthy of report.

CASE-REPORT

A 36-year-old spinster, who worked as a machinist, first ought advice early in 1946 for a maculopapular rash on the ace which later spread to the trunk and arms, and for loss of nergy and weight. In June, 1947, she was admitted to hospital with a diagnosis of lupus erythematosus. She improved n treatment with penicillin and bismuth.

During the next 18 months she continued to lose weight nd developed stiffness, pain, and swelling of her knees, nkles, elbows, and wrists. In April, 1949, she was readmitted with left-sided pleuritic pain and an exacerbation of her rash; this was thought to be an acute phase of disseminated lupus erythematosus. X-ray examination showed shadowing at the base of the left lung. There were no tubercle bacilli in the sputum, and the white-cell count was 5000 per c.mm. with a normal differential count. Both pulmonary and cutaneous lesions responded to penicillin, but she developed alopecia of the scalp. On discharge 6 weeks later her lungs were radiologically normal.

The disease appeared quiescent until June, 1950, when she relapsed with arthritis, loss of weight, and recurrence of the rash. In August she was again admitted and improved on streptomycin and penicillin, but loss of hair increased.

In April, 1951, she again relapsed and in June she was transferred to the Royal Hospital, Sheffield, for cortisone treatment.

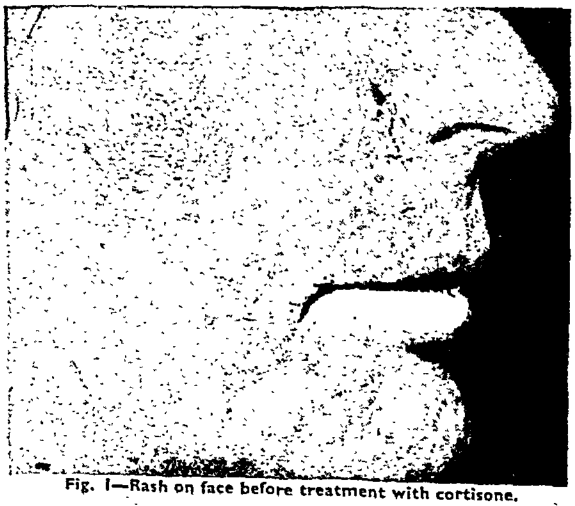

Fig. 1—Rash on face before treatment with cortisone.

She was seriously ill, with a temperature of 102°F, and a pulse-rate of 120. A rash was present over the face, scalp, suprasternal notch, and hands; it was deep red, and maculopapular over the malar regions of the face, becoming confluent toward the eyebrows, but there was no butterfly distribution. The eruption on the hands was less vascular, but over the scalp and suprasternal notch it resembled that on the face (fig. 1).

The blood-pressure was 108/48 mm. Hg. There was no clinical evidence of endocarditis. Slight periarticular thickening of both wrists and typical rheumatoid swelling of the fingers were present. The knees were similarly affected and movement of all these joints was painful and limited.

The blood picture was as follows: hæmoglobin 70% (10·5 g. per 100 ml.), red cells 3·5 million per c.mm., leucocytes 1000 per c.mm. (polymorphs 57%, lymphocytes 11%, monocytes 15%, band cells 17%), platelets 64,000 per c.mm. The erythrocyte-sedimentation rate was 101 mm. in 1 hour (Westergren); clotting-time 9 min. (Lee and White); and bleeding-time 9 min. (modified Ivy). At first the Haserick culture showed no clumping or lupus erythematosus cells, but these were later present. The urine repeatedly contained protein, granular casts, and red blood-cells. An X-ray film of the chest showed increased vascular markings at the left base, but no other abnormality (fig. 2).

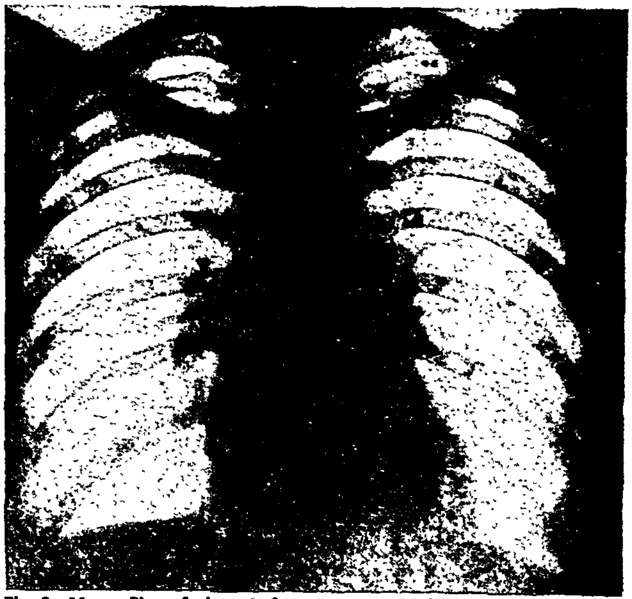

Fig. 2—X-ray film of chest before treatment with cortisone showing increased vascular markings only.

During an initial observation period of 10 days without treatment the rash faded slightly but the temperature remained elevated. But as no permanent improvement seemed likely a total of 2·35 g. of cortisone acetate (Merck) was given by intramuscular injection over a period of 21 days. Within the first 3 days the rash cleared and the joints became painless. After 8 days she was apyrexial, and all that remained of the rash was some residual staining (fig. 3). On the 17th day of treatment, when she was receiving 100 mg. on alternate days, joint pains returned and the pulse-rate and temperature rose. Dosage was increased to 100 mg. daily, but the pyrexia became even greater and cortisone was stopped. Although the rash did not return with its original severity, a diffuse solar dermatitis developed on exposure to direct sunlight, and there was further loss of hair.

The albumin/globulin ratio was reversed during the illness and gradually diminishing urea-clearance values suggested progressive renal damage. Other investigations were normal.

The patient had a slight and almost unproductive cough; fine scattered crepitations were heard over both lung fields. Although still febrile, she looked and felt quite well. An X-ray film showed miliary infiltration throughout both lungs (fig. 4).

Miliary tuberculosis was thought more likely than pulmonary lupus erythematosus; though the sputum, gastric washings, and urinary deposit showed no acid-fast bacilli on direct examination, guineapig inoculation was positive. Tubercle bacilli of human type were cultured from gastric washings.

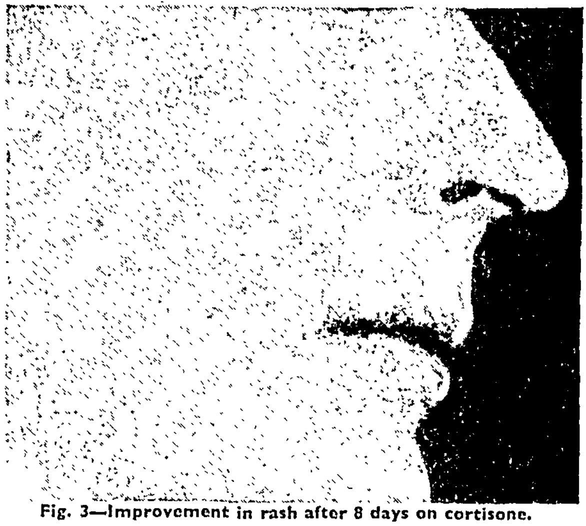

Fig. 3—Improvement in rash after 8 days on cortisone.

Streptomycin and p-aminosalicylic acid (P.A.S.) were given; she had 1 g. of streptomycin and 18 g. of P.A.S. daily for 3 months. Her temperature fell steadily and finally settled below 99°F. She became extremely well and gained 8 lb. in as many weeks, and her hair grew rapidly. There were now no abnormal physical signs in the lungs, but the miliary infiltration on the X-ray film did not change appreciably (fig. 4).

DISCUSSION

There is now good evidence that A.C.T.H. and cortisone control relapses in disseminated lupus erythematosus, but they do not seem to be curative.

Soffer et al. (1950) reported fourteen cases in an acute phase where the diagnosis seemed indisputable. Both A.C.T.H. and cortisone had effects; only 1 patient showed no response at all and died of a fungus pneumonia. The first response was usually a fall in temperature and then a fading of the rash. Withdrawal produced relapse, and a maintenance dose was necessary. Complications in this series were hypertension, striæ of the skin, œdema, mental depression, pigmentation, hirsutism, alkalosis, and diabetes. The only pulmonary complication was the fatal fungus pneumonia. Plotz et al. (1950) discussed three cases including one of Libman-Sach endocarditis. Initial response to A.C.T.H. was followed by fatal relapse in each case. Haserick et al. (1951) used the drugs in 16 cases of disseminated lupus erythematosus and found that doses of cortisone in the region of 100 mg. hourly for short periods were necessary in a crisis. Baehr and Soffer (1950) mention some well-known complications but no pulmonary ones. Brunsting et al. (1951) point out that the drugs may mask serious complications such as peritonitis, pancreatitis, and septicæmia.

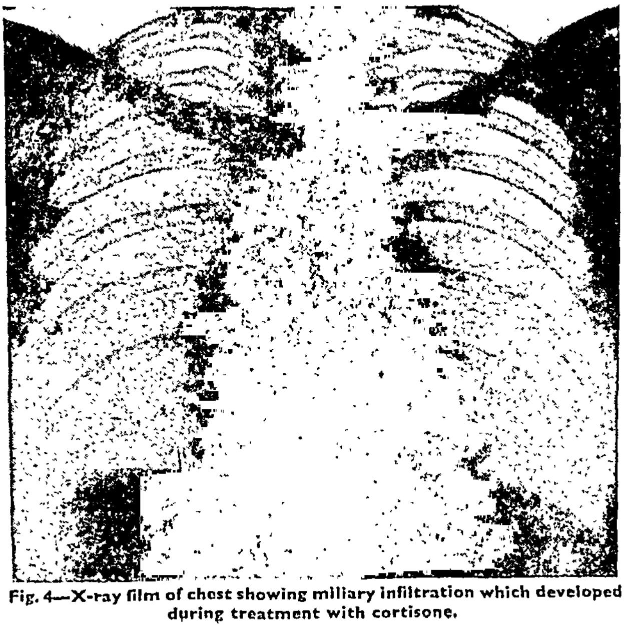

Fig. 4—X-ray film of chest showing miliary infiltration which developed during treatment with cortisone.

Keil (1933) thought that there was no conclusive evidence of a relation between disseminated lupus erythematosus and tuberculosis. Dittrich (1949) reported a case of disseminated lupus erythematosus in which pulmonary disease was demonstrated radiologically. This resolved and there was no lesion at necropsy; it was probably hæmorrhagic or allergic and not tuberculous.

There is experimental evidence that A.C.T.H. and cortisone facilitate the spread of tuberculosis in the lungs of susceptible animals by inhibiting fibroplasia (Cummings 1951, Hart and Rees 1950, Michael et al. 1950, Spain and Molomut 1950). Recent work shows that these hormones may sometimes have this effect in man.

A patient with rheumatoid arthritis and hepatic cirrhosis was given A.C.T.H. and cortisone by Fred et al. (1951). The arthritis improved, but he developed tuberculous bronchopneumonia and died. The sputum was positive, but there was no clear proof that he was free from tuberculosis before treatment began. King et al. (1951) reported rapidly progressive pulmonary tuberculosis following cortisone in a patient with rheumatoid arthritis, but there was no pathological proof that this complication was tuberculous. Popp et al. (1951) had a patient in whom cortisone probably activated a quiescent tuberculous focus known to exist before treatment. The sputum had been consistently negative for many years but it became bloodstained and acid-fast bacilli were found after cortisone therapy.

Our patient had been under observation for 4 years with no evidence of pulmonary tuberculosis. Lung changes were reported in 1949, but they resolved. The chest films immediately before cortisone treatment did not suggest active or latent tuberculosis. However, unequivocal signs of miliary tuberculosis followed a short course of cortisone; the radiological appearances were typical and tubercle bacilli were present in sputum and urine. This sequence may be explained in one of three ways:

(1) Miliary tuberculosis was in fact present before treatment began, but its presence was unrecognised.

(2) It developed after treatment began, but was not in any way attributable to cortisone.

(3) It developed from an unsuspected and latent focus as a direct result of cortisone therapy.

The first two possibilities cannot be excluded, but in the circumstances the third explanation seems to us the most likely. This case supports the belief that disseminated lupus erythematosus may have an affinity with tuberculosis, and confirms reports that these hormones are potentially dangerous in active or latent tuberculosis. A careful search for such foci should be made whenever A.C.T.H. or cortisone therapy is contemplated and this watch should be maintained during and after treatment.

SUMMARY

A woman of 36 was given cortisone for disseminated lupus erythematosus. She developed miliary tuberculosis with positive sputum and urine. She had previously been under observation for 4 years and no evidence of tuberculosis had been found at any time.

It seems likely that the disease spread from a latent and unsuspected focus directly activated by cortisone. Published reports are quoted in which the use of A.C.T.H. and cortisone was followed by lung disease, which in some cases was definitely proved to be tuberculous.

We should like to thank Dr. C. Gray Imrie for his kindly criticism and for permission to publish this article.

ADDENDUM

Since this article was submitted a similar case has been reported by Walker (1952).

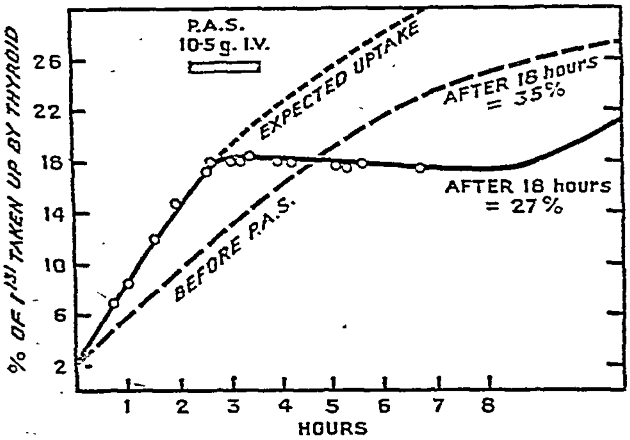
Preliminary Communication

DETERMINATION OF THE ANTITHYROID ACTION OF PARA-AMINOSALICYLIC ACID USING RADIOACTIVE IODINE

MYXŒDEMA associated with *p*-aminosalicylic acid (P.A.S.) therapy was first described by Clausen and Kjerulf-Jensen[1] in 1951. They reported three patients in whom signs of myxœdema disappeared when P.A.S. was stopped. In England Komrower[2] has described a similar case of a child aged $8^{1}/_{2}$. Kjerulf-Jensen and Wolffbrandt[3] have since shown that rats fed with P.A.S. and *m*-aminophenol developed moderate cellular hyperplasia of the thyroid gland.



Inhibition of uptake of I^{131} in the thyroid gland after 10·5 g. of P.A.S.

Using radioactive iodine (I^{131}) according to the method of Astwood and Stanley,[4] I have studied the accumulation of iodine in the thyroid gland during P.A.S. therapy. The radioactive material in the gland was measured by direct external application of a Geiger-Müller counter.

In the accompanying figure the broken line shows the rate of iodine uptake after an oral dose of 0·1 millicurie of I^{131} in a patient with pulmonary tuberculosis who had had no chemotherapy. The curve reached a maximum after 24 hours, when in this case 35% of the dose given had been taken up by the thyroid. The first part of the unbroken line shows the uptake of radioactive iodine in the same patient after an identical dose, but after 3 weeks' P.A.S. therapy. After $2^{1}/_{2}$ hours a total of 300 ml. of sodium P.A.S. (1 ml. = 0·035 g. of P.A.S., the total dose being 10·5 g.) was given by intravenous infusion over a period of $1^{1}/_{2}$ hours. After about 45 minutes (when approximately 150 ml. had been given) the uptake of iodine in the gland stopped. The curve remained stationary for a further 4 hours. After 15 hours, however, the thyroid had regained some of its ability to take up iodine. The inhibitory action of P.A.S. ceased probably before the non-protein-bound iodine was excreted. This is in accordance with the findings in assays with propylthiouracil. The steeper rise of this curve compared with the first one may be the result of compensatory enlargement of the gland due to an increased formation of thyrotropic hormone in the pituitary gland. This increase is caused by a decrease of thyroid hormone in response to antithyroid substances.[5] If intravenous P.A.S. had not been given after $2^{1}/_{2}$ hours the dotted curve would have been obtained.

Similar curves were obtained in two other patients, although the time which elapsed before the inhibition of iodine uptake was variable. In one patient the iodine accumulation ceased as early as 20 minutes after the intravenous infusion of P.A.S. began, when only 2·1 g. had been given. This patient had been having 10 g. of P.A.S. by mouth daily for 14 days.

The concentration of P.A.S. in the blood after the intravenous infusion of 10·5 g. is about 25 mg. per 100 ml.; after 6 hours it falls to 3 mg. per 100 ml.

When P.A.S. is given therapeutically, a certain concentration in the blood will inhibit the synthesis of thyroxine in the same way as thiouracil. Therefore doses of P.A.S. in excess of the patient's thyroid sensitivity may give rise to myxœdema, and before P.A.S. is given the possibility of such individual sensitivity should be considered.

A detailed account of the antithyroid action of P.A.S. will be published later.

From the department of Dr. Gösta Birath,
Söderby Hospital,
Uttran, Sweden

Reviews of Books

The Sensations

Their Functions, Processes, and Mechanisms. HENRI PIÉRON, M.D., professor of the physiology of sensation, Collège de France, Paris. Translated by M. H. Pirenne and B. C. ABBOTT. London: Frederick Muller. 1952. Pp. 469. 42*s*.

THE first French edition of this book was published in 1944, and in this English translation much work which has since been done on the physiology of sensation has been incorporated. The object of the book is to survey facts which have been discovered about the physiology and psychology of the spinal senses and of cutaneous and proprioceptive sensation, and to review the many theories which have been proposed to account for them. It is based on lectures given at the Collège de France by the author, who has made many original contributions to the physiology of vision. Neither the subject nor the style makes this an easy book to read; but, though it is unlikely to be of great interest to clinicians, it should be valuable to physiologists and psychologists who are working on any aspect of sensation.

Handbook of Diseases of the Skin

HERBERT O. MACKEY, F.R.C.S.I., member of the dermatological section of the Royal Academy of Medicine, Dublin. Dublin: Fallon. 1952. Pp. 216. 7*s*. 6*d*.

AUTHORS of books intended primarily for students need to obey three essential rules: the content must be confined as far as possible to facts; the whole subject should be systematically covered, so that the student can form an impression of its scope; and there must be a sense of balance, so that common disorders are not omitted or rarities given too much attention. This book conforms fairly well to the first of these tenets but less well to the second and third.

Thus the chapter titles do not indicate what lies within them: the chapter headed "*Tinea Circinata*" includes all forms of ringworm, the chapter headed "Parapsoriasis" deals as well with three other conditions, while the chapter headed "Prurigo" covers also pruritus ani but not pruritus vulvæ or generalised pruritus. The earliest chapters adequately cover anatomy, embryology, physiology, and pathology; then follows symptomatology, and a useful list of diagnoses based on morphology. The list of common skin diseases based on their distribution cannot be recommended, however, because of the many exceptions. Diagnosis must be made on history, arrangement, and morphology as well as on distribution; and in any case a list of 22 different trunk lesions does not guide the student far towards diagnostic lucidity. Readers in Great Britain will hardly agree that "too much meat and fresh bread are common errors of diet"; and the injunction that "worry or anxiety should be forbidden" invites the riposte "How?" Many would disagree that Bowen's disease should be treated by surgery, diathermic destruction, or radium; and no mention is made of good results obtainable with carbon dioxide snow. Some 36 photographs are scattered indiscriminately through the book, without references in the text. Some are good—for example those of pemphigus and molluscum contagiosum—others very poor.

Vaccination par le B.C.G.

R. MANDE and A. HUËT, Station-Pilote B.C.G. du Centre International de l'Enfance, Paris. Paris: *Centre International de l'Enfance, Travaux et Documents*—III. 1952. Pp. 168. Fr. 750.

THIS book is a documentation of work done in the past three years at the Station-Pilote B.C.G. du Centre International de l'Enfance, founded in Paris by UNICEF in 1948. The investigators' purpose has been to compare and contrast the effects, on human beings, of several commonly used tuberculins and B.C.G. vaccines. The first part of the book records comparative studies of the intradermal Mantoux test (with different doses of tuberculins from France, Denmark, and Sweden), the Moro-patch, the *timbre tuberculinique*, the Pirquet with and without adrenaline, and the modified Trambusti as currently used in Finland. The intradermal, scarification, and multiple-puncture techniques of vaccination were compared in relation to tuberculin allergy, local lesions, and frequency of complications (ulcer, abscess, adenitis). The second part is concerned with the effects of variations in the batch, source, and concentration of the vaccine itself; the influence on fresh vaccine of time (up to 24 days) and temperature of storage (20°C for 3 days), and on dry vaccine of storage for 1–6 months at 4°–5°C or for 1–2 weeks at 20°C; and the comparison of fresh and dry B.C.G. prepared from the same culture.

The authors recognise that many relatively simple facts about B.C.G. are still unknown, and they have made so great an effort to answer important questions that it seems ungrateful to question the reliability of their data and conclusions. But insufficient information is given on some of the critical details of technique. Who were the subjects and how were they selected? How comparable were the studied groups? How uniform was the technique from series to series—and within each series? What precautions were taken to avoid biased observations?

Writing on the effect of storage temperature on fresh vaccine, for example, they say that "it is important that vaccine, after it is put in ampoules, should be kept at a low temperature (4°–5°C) in order to preserve a sufficient proportion of living bacilli." But the data which follow concern 76 subjects given B.C.G. kept for 10 days at 4°C, and 74 given a *different batch* of B.C.G. stored in the ice-box for 7 days, and then at 20°C for 3 additional days. Post-vaccination tests (time, test, and dose not stated) revealed 80·4% to be positive in the first group, 90·5% in the second. Such "paradoxical" results, the authors explain, do not justify concluding that there were sufficient living bacilli in the heated vaccine to sensitise the subjects, as "it is known that dead bacilli can produce allergy." They feel that no conclusion should be drawn from this study because "the circumstances, in fact, did not permit assembling homogeneous groups, of equal age, nor to use the same vaccine on the same day, nor to have all the vaccinations given by the same vaccinator. Many other variables than temperature [of storage of the vaccine] could have interfered, and as it is impossible for us to take each of them into consideration, it seems preferable for us not to decide the issue."

When, however, the results were not considered paradoxical, the authors often draw quite definite conclusions without indicating whether the "circumstances" in these cases allowed for assembling more comparable groups and/or for technique any less irregular.

It is difficult to imagine how some of the studies, as the example cited, could have been expected to provide reliable data; and unfortunately many of the results must therefore be considered inconclusive.

Child Psychiatric Techniques

LAURETTA BENDER, B.S., M.A., M.D., professor of clinical psychiatry, New York University College of Medicine. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 312. 60*s*.

THIS is neither a textbook of child psychiatry nor a manual for the therapy of maladjusted children. It might perhaps be likened to the working notebooks of a skilled and experienced team. The chapters, some of them taken from work already published in the journals, reveal the thrust of a number of highly intelligent minds, not the least being the chief author's late husband, Paul Schilder. He came to his original work with difficult children from the unusual background of organic neurology combined with Freudian psychoanalysis, and traces of both these disciplines show in his approach to the work.

After a general survey of the way in which child psychiatry became a clinical study in its own right—borrowing something from organic neurology, adult psychiatry, mental deficiency, and pædiatrics in medicine, and from pædagogics and delinquency in the educational and social fields—Professor Bender describes the range of techniques in use at the Bellevue Hospital in New York, with its ward for 50 problem children. Almost any kind of problem is accepted for short-term study, and some children remain resident for sustained therapy. A chapter, rather too far on in the book, describes succinctly some aspects of day-to-day routine in the ward. A later chapter describes various projects, some educative and most of them planned to reveal conflicts which are distorting the child's sense of reality. This picture of the interplay of emotion in a group of gravely disturbed children is so vivid that it makes painful reading. In describing the school, which is part of the regular programme of activity, the authors discuss the question of group activity and the reactions of the children themselves towards symptoms in others.

Another considerable part of the book is devoted to work on Bender's Gestalt test, both as a projection test and as a measure of distortion of the body image. This latter concept is given great weight as being a significant part of the inner disturbance especially in the schizophrenic child. In the Gestalt chapters the diagrammatic arrangements are tiresomely out of line with the text; and the one chapter dealing more fully with the interpreted material from a single child is a little disappointing.

The book, however, is full of matter, often controversial, and covers in a wide sweep all the techniques available for a very diverse group of troubled children. A further volume might well deal more fully with less material.

A Textbook of Midwifery (15th ed. London: A. & C. Black. 1952. Pp. 586. 30*s*.).—This fine standard work is in its fortieth year, and its fifteenth edition. We all mature, but not all of us reach middle age with a plastic and unprejudiced outlook. A good textbook, however, must keep this quality above all others; and that it can only do if it is regularly revised and scrutinised by its authors. To keep their book abreast of reliable recent observation and practice Prof. R. W. Johnstone and Prof. R. J. Kellar have each revised the entire text. It is as factually informative as ever, and written clearly and precisely, and without condescension. Changes have been made in the section on maternal metabolism during pregnancy (a subject on which knowledge is always growing). There is a very good new paragraph on the reassurance and instruction of the mother about the course of events in labour (which should be rehearsed) and on the value of teaching her to relax. A.C.T.H. is mentioned in the section on pre-eclampsia; and the chapter on radiology has been revised by Dr. J. Z. Walker.

THE LANCET

LONDON: SATURDAY, JULY 19, 1952

Delaying Action

IN the matter of pay and prospects for doctors in the Civil Service, the Treasury is fighting one of its characteristic delaying actions. The operations now in progress began nearly three years ago when in September, 1949, a deputation to the Chancellor's department pointed out that many of the abler young doctors were leaving the Ministry of Health because remuneration was insufficient, and that Government service could not hope to attract enough recruits of the proper calibre unless it offered salaries much closer to those obtainable in the National Health Service.[1] On behalf of the Joint Committee formed by the Institution of Professional Civil Servants, the Ministry of Health Medical Staff Association, and the British Medical Association, this deputation put forward a claim for pay on a scale that it thought appropriate to those at present in the service, and likely to secure suitable entrants for the future. After six months this claim was firmly rejected by Sir STAFFORD CRIPPS.[2] He fully recognised, he said, the need for maintaining the efficiency of medical establishments, and indeed of other important establishments which were at present below strength; but in his view it was then even more important to maintain the policy of wages stabilisation, which would be jeopardised if exceptions were made to the general rule. He added that a claim by Civil Service doctors must be regarded as a Civil Service claim "to be dealt with on the basis of the policy applied to the Civil Service generally." However, by way of concession, he proposed to appoint a committee to go into the question of "the remuneration and the general salary structure of Civil Service doctors" and advise the Government on what changes can be made "when economic conditions allow improvements to be made in remuneration generally."

The history of that committee is not a happy one. Originally it was to consist of four administrators and only two doctors: and, as we remarked at the time, it looked rather like a mechanism for repeating the Chancellor's own opinions after a decent interval. Medical protests led him to say that he would consider nominations by the Institution of Professional Civil Servants and by the British Medical Association, but he neither accepted the doctors nominated nor gave those bodies a chance to put forward other more acceptable names. As finally constituted, the Howitt Committee did indeed have four medical members, and they were all men much respected in the profession; but it nevertheless embodied the Treasury's decision not to have a representative committee making a fundamental inquiry. Its all too brief report, issued last autumn, reads like a departmental memorandum rather than the findings of a public commission; for in stating its own conclusions it neither summarises nor comments on the cogent contrary arguments submitted for its consideration. With much of what the committee said we are ourselves in agreement[3]; but neither its appointment nor its report has demonstrated to the profession or the public that the problem has had the full and judicial examination it deserves.

An impasse has now been reached. The Joint Committee, arguing that the Howitt scales are additionally unacceptable now that the Danckwerts award has improved remuneration for general practitioners, has asked for arbitration—which Civil Servants above a certain grade cannot claim as a right. To this Mr. BOYD-CARPENTER, for the Treasury, replied on April 17 that the Howitt Committee was a completely independent body, and to refer the question to an entirely fresh arbitration tribunal, before making any trial of the salaries which the committee recommended, would be a wholly unjustifiable reflection on its competence. "We shall," he said, "be very willing to give the matter further consideration if, after the rates recommended by the Howitt Committee have been given a fair trial, they are found insufficient to attract the doctors we require." The Treasury realises, he added, that it will be necessary to consider whether the effects of the Danckwerts award necessitate adjustment in the Howitt scales. So far, so bland. But unfortunately it now appears that the time arranged for this much-needed review of the success or otherwise of the Howitt salaries is "not later than December, 1953"—i.e., rather more than four years after the Joint Committee put forward its claim. The delaying action, in fact, is to continue. The Treasury, we cannot help thinking, does not really mind very much if Civil Service medicine deteriorates, just as it did not mind about general practice deteriorating. By resisting the claims of general practitioners for an equitable settlement it did quite incalculable harm to the National Health Service in the early formative years —without, in the long run, saving the nation a penny. Further harm has been done to the N.H.S. already, and much more will be done in future, because the Treasury does not enable the Ministry of Health to pick the best men for its work at the centre.

From the final exchange of letters described on p. 141, it will be seen that until such time as the Treasury feels able to discuss some alternative proposals, the British Medical Association is going to refuse to accept "any further advertisements for medical officer appointments in the Civil Service." When a similar decision was taken in May, 1950, in an earlier phase of these negotiations, we explained[4] that, as an independent journal, we differ from the B.M.A. on the constitutional propriety of rejecting advertisements as a means of inducing a Government to change its policy: we thought, and still think, that the professions should set an example by refraining from all measures that may be construed as "direct action" for political or semipolitical purposes, since this kind of pressure has inherent dangers for a democracy. On principle, therefore, we cannot refuse to publish advertisements of Civil Service appointments, unless or until the Government can be shown to have violated an agreement. On the other hand, like the Joint Committee, we have lost all confidence in the Treasury's intentions, and we wish to associate ourselves most strongly with the committee's request that the subject should be reconsidered much sooner and more objectively than is now proposed. Though we shall not deny the Government the right (if they wish) to advertise their medical posts in our columns, we think it would now be only proper that any such advertisements should be accompanied by an editorial statement of the present objections to their being filled. Accordingly, in the (perhaps unlikely) event of advertisements being submitted, we intend to add to each of them an indication to possible applicants that conditions of remuneration and promotion for doctors in the Civil Service have not yet been satisfactorily settled, and that the B.M.A. has made these posts the subject of an Important Notice.

Diagnosis of Infective Mononucleosis

THE clinical guises of infective mononucleosis (glandular fever) are diverse, as TIDY [1] showed many years ago. The form with enlargement of cervical glands predominates, and, especially in outbreaks, this form may cause no diagnostic difficulties; but in atypical forms, at least the early stages of the illness do not resemble the usual conception of the disease. Thus, meningeal,[2] encephalitic,[3] and other neurological syndromes common to a number of virus, or presumed virus, infections may so overshadow other clinical features that infective mononucleosis is not at first considered; or the illness may take the form of a generalised febrile and toxic state [1] (sometimes severe and possibly fatal from hepatic and renal failure [4]) which may precede adenopathy by many days; or adenopathy, if it appears early, may be so slight as to be overlooked. On the other hand, symptomless infections occur [5] [6] and are discovered only as the result of routine blood-counts, followed, if these are suggestive, by heterophil-antibody (Paul-Bunnell) tests, in patients admitted to hospital for other conditions. Again, the blood picture early in the attack may not reveal the characteristic atypical lymphocytes. Nor is the presence of these cells in the peripheral blood confined to infective mononucleosis. In a number of virus infections and in pertussis the blood picture is similar though, to the expert hæmatologist, not identical. Finally, even in a true case of infective mononucleosis the heterophil-antibody test may be negative or else positive only in a titre regarded by the serologist as insignificant. Nevertheless, it is generally accepted that, especially in sporadic cases, a characteristic blood picture and preferably a significantly positive Paul-Bunnell test are required for a positive diagnosis. BENDER [7] suggests that the atypical-lymphocyte count should be greater than 1000 per c.mm.; but this in itself is not diagnostic, and he recommends more precise differentiation of mononuclear cells by supravital staining [8] since this number of atypical lymphocytes "may indicate rubella, rubeola (measles), varicella or mumps." Supravital staining is not, apparently, generally used by hæmatologists; yet BENDER finds that in smears prepared for routine differential counts the atypical cells seldom present recognisable characteristics: "only a thin even spread makes these cells easy to identify."

As to the diagnostic *tertium quid*, the heterophil-antibody test, BENDER points out that if cases are classified as serologically negative on the basis of a single test during the first week of the illness, "the results are understandable." In his own experience of 146 patients in hospital and 194 ambulant patients, aged 17–32 years, who were followed up clinically and hæmatologically, "all patients with a positive blood smear have shown a diagnostic titre of heterophil antibodies provided serial tests were made through the second week of the disease." But what is a diagnostic titre? PAUL'S [9] opinion, in 1941, was that a titre of 1 : 64 was nearly always diagnostic, and one of 1 : 32 suggestive. BENDER selects a titre of 1 : 56 as positive; "but in very few hospitalised patients did a titre of 1 : 896 fail to develop," and he concludes that if the test is not positive at the beginning of the second week "other leads should be pursued." This time-limit may suffice in most cases; but in some forms of the disease—notably that commencing with a neurological syndrome and TIDY'S febrile type—heterophil antibodies may appear only in the later stages or even in convalescence. Probably, as with other agglutinin tests, a rising titre is more important than the initial absolute titre unless this is high. Some titre of heterophil antibodies may persist for quite a long time after a clinical attack; but in these circumstances, and in symptomless infections, the titre does not rise. BENDER reminds us that, despite numerous atypical clinical pictures, sore throat and adenopathy represent the clinical prototype of the disease; and when these are absent he calls for stricter laboratory checks, and especially repeated heterophil-antibody tests, on which he pins his faith.

Employment of Disabled Youth

THE Medical Research Council memorandum on Employment Problems of Disabled Youth [10] is a penetrating study of a matter of consequence to the whole nation. Professor FERGUSON and his colleagues examine the many difficulties which beset the handicapped adolescent, and conclude that much more could and should be done to help him in his effort to keep up with his more fortunate fellows. They think that "there can be few more promising fields for the practice of constructive medicine than those concerned with the problems of disabled youth . . . for the successful settlement in employment of a disabled young person provides him at once with a means of livelihood and a satisfying and constructive job, surely two of the greatest of human rights."

The investigators set out to discover to what extent disabled young people in Glasgow are unable to earn a living, what kinds of disability interfere most seriously with their working capacity, how far social and environmental factors contribute to their difficulties, and whether any amelioration is possible. The first study concerned 579 young people, under nineteen years of age, who had registered in Glasgow under the

Disabled Persons (Employment) Act, 1944, as "disabled persons" who were substantially handicapped in getting and keeping suitable work. The second study dealt with 408 physically handicapped young people who were pupils of the Glasgow special schools at the end of their school career, and who had mostly left school a full three years before the date of the survey. Control figures for these two complementary studies were provided by a similar survey, also made in Glasgow, by Ferguson and Cunnison,[11] of a large group of normal adolescents. Only 30% of those who attended special schools for the physically handicapped were registered under the Act, but it must be remembered that the reason for attending a special school is educational need, whereas a disabled person is likely to register because he has difficulty in obtaining and holding a suitable job. A considerable proportion of both groups had failed to avail themselves of necessary medical care—often because they had grown tired of doctors and hospitals—and 8% in the first group and 9% in the second required some form of medical appliance. In both groups unemployment was common; at the time of the survey 19% of the combined total were out of work. Those with organic diseases of the nervous system, particularly epilepsy and cerebral palsy, and the mentally retarded, found it especially hard to get work, while disabilities caused by respiratory disease, infantile paralysis, or deafness were less likely to cause unemployment. Not only is the unemployment-rate higher among the disabled, but the proportion engaged in non-manual work and in skilled or semi-skilled work is lower, while the proportion in unskilled manual work, often heavy in its physical demands, is twice as high as in normal youths. Many of these disabled people were therefore doing work far beyond their physical capacity, those with cardiac disease or tuberculosis, for instance, often undertaking heavy manual labour.

Each disabled person has his own problems, often intensified by his social background, and each requires careful individual consideration. Age, too, affects the employment picture:

> ". . . the proportion unemployed, for instance, is relatively low up to the age of 17 and rises steeply between 18 and 20. The proportion in non-manual work rises up to 19 years. The 16-year-old can easily find an unskilled job near his home; at first it may be within his physical compass and is often better paid in the initial stages than the job requiring special skill. It is only later, at 18, that he finds that the unemployment rate has doubled and that demands on his physical strength are steadily increasing. Such youths scramble through one exhausting job after another, and they are often hard put to it to avoid physical collapse and prolonged unemployment."

The way in which work was obtained was likewise important. When the young person found it himself he favoured office work; relatives or friends tended to guide him into skilled or semi-skilled manual work; and the employment exchange usually gave short-term unskilled work, largely because the exchanges had to find work when other means failed. When a disabled person registered on the advice of the authorities of special schools, the proportion in skilled and semi-skilled manual work was satisfactory. Those who were advised to register by their doctors were usually severely disabled, and their unemployment-rate was high, but when the stimulus came from their employers unemployment was rare. Much of the most stable and satisfying work was skilled office or skilled manual work. The survey also showed that 20% of the young people changed their jobs unusually often; unskilled workers and the mentally retarded did so most frequently, and the older the worker the less likely was he to change. Girls changed their jobs more light-heartedly than boys.

Deficient schooling adds greatly to the burden of the disabled child. If the deficiency is great, he may be denied the choice of office work, and he is usually forced into manual labour: should he be unfit for this he becomes either ill or unemployed. The educational standard was closely related to inability to perform non-manual work and to the unemployment-rate. Unfortunately education in special schools still carries a stigma of inferiority in the eyes of both the pupil and his potential employer. Professor Ferguson and his colleagues think it essential to secure the highest possible standard of education for disabled children, especially in the special schools, so that the disability of gross educational poverty shall not be added to that of physical impairment. The best time for a disabled youth to start work is when he leaves school, for then his attitude to employment is positive and full of enthusiasm. But

> ". . . constructive action is too often delayed and, as the months pass, the youth drifts into unskilled manual labour. At first it is comparatively well paid, and the youth, no longer a schoolboy, resents advice which urges him to take a job that may be skilled but which brings him in a smaller wage. Later still, when illness or idleness have opened his eyes to the hazards of unskilled labour and he sees his friends in skilled work now earning more than he can, disillusionment and bitterness often give way to cynicism or dissolve finally into apathy. The crisis of leaving school is never repeated. These surveys, which so often saw the hopes of fourteen turn to the cynicism of twenty-one, suggest that the striking success gained in resettling deaf young folk in Glasgow could be attained in many other disabilities if the same deep insight and interest in the special problems of youth were shown."

Other factors which have an important effect on employment include bad housing conditions, which make the task of reablement far harder; 30% of Ferguson's badly housed group were unemployed, and only 11% were doing skilled work. Unhappy homes made for more unemployment and frequent changes of job. The investigators conclude that the future of the disabled child is so precariously balanced that the parents' attitude is usually the decisive factor: where it is apathetic, unemployment is common and the general outlook unfavourable, but where the child is blessed by the security of a good home and enjoys real family life, even severe disabilities can be overcome.

This valuable report expresses disquiet at our failure to find these young people the right work. Of those registered under the Disabled Persons (Employment) Act only 26% were receiving suitable training; 22% were apprenticed in a variety of callings, non-manual and manual, and only 4% were attending training courses arranged by the Ministry of Labour and National Service. Many of the others bitterly resented the frustration of hopes which had been raised by the posters about training courses displayed in the employment exchanges. It is disappointing that, at a time of full employment, a greater effort has not been made to provide for disabled young people. Team-work is the key: each disabled person presents a personal problem which often can be solved only if all those concerned—parents, family doctor, school doctor, consultants, school teachers, social workers, employment officer, and sometimes potential employers—join in considering the facts and in making an appropriate individual policy by discussion. It is important for one member of the team, preferably the employment officer, to be given the responsibility of arranging training and employment without delay. Such is the logical approach advocated and practised by FERGUSON in Glasgow, and by others, with conspicuous success. Insufficient progress in helping disabled youth means a larger and harder core of unemployment in years to come, when it seems likely that the strain on the working population will in any case be great. FERGUSON and his associates point to four immediate needs: (1) improvement in education; (2) satisfactory settlement on leaving school; (3) more training courses; and (4) intensive medical and surgical treatment where this is required. All these needs can, and should, be met.

Annotations

CHLORAMPHENICOL AND THE BLOOD

PATIENTS receiving antibiotics have not escaped being troubled by side-effects; but these have been limited more or less to the occasional urticarial reaction, nausea, and, with streptomycin, deafness. Chloramphenicol, however, has been suspected of affecting the blood-forming tissues; and, as we reported last week,[1] the Food and Drug Administration has started a nation-wide survey in the U.S.A. after receiving reports of many cases of aplastic anæmia from this cause. Hitherto only six cases of bone-marrow depression following the use of chloramphenicol seem to have been published; but now Wilson et al.[2] have added to this list two cases of aplastic anæmia, in one of which the patient died.

Kracke and Parker[3] found that substances having in their chemical structure a benzene ring with an attached amino or nitro group were likely to affect the bone-marrow adversely. Chloramphenicol has this type of structure. Gill[4] described two cases of granulocytopenia, both in infants who were being treated for acute salmonella infection. One developed granulocytopenia after 12·3 g. of chloramphenicol had been given in twelve days, the other after only 1·75 g. in two days; in both the granulocyte-count promptly returned to normal when chloramphenicol was discontinued. Volini and co-workers[5] in the U.S.A. had three cases of neutropenia among patients treated with chloramphenicol for up to nineteen days, and one patient with typhoid fever had anæmia as well; in this patient the blood-count took three weeks to return to normal, but the others recovered very quickly. Rich et al.[6] reported the first fatal case. The patient was receiving chloramphenicol regularly for a urinary-tract infection; treatment had been continued for fifteen weeks, about 57 g. of the drug having been given. The first sign that something was wrong was the appearance of purpura; the patient eventually died and necropsy showed an aplastic bone-marrow.

The two cases reported by Wilson and his colleagues had also had long courses of chloramphenicol. These patients were members of a group of 62 who were receiving chloramphenicol regularly in a trial of the drug for the control of chronic bronchopulmonary suppuration; the dose was small—1 g. twice weekly. The first patient had been taking chloramphenicol for twenty-six weeks when the first unusual symptoms—epistaxis and purpura—appeared. Her hæmoglobin was reduced to 6 g. per 100 ml.; the white-cell count was 1110 per c.mm. with 8% neutrophils; platelets were 15,000 per c.mm. The bone-marrow was hypocellular; and most of the cells were lymphocytes and plasma and reticulum cells. It was clear that she had aplastic anæmia, and blood-transfusion was begun; but the hæmorrhages spread rapidly and became uncontrollable, and the patient died. Necropsy revealed generalised marrow aplasia. The second patient had severe epistaxis after receiving chloramphenicol for three months, but the significance of this symptom was not appreciated; the blood was not examined, and treatment with the drug was continued for another two months. At this stage, when the patient had received over 50 g. of chloramphenicol, she had severe epistaxis, and purpura appeared. Her hæmoglobin was reduced to 10 g. per 100 ml.; white cells were 9800 per c.mm. but there was only 33% of polymorphonuclears; platelets were greatly reduced to 9000 per c.mm. The bone-marrow was hypoplastic with unusual numbers of lymphocytes and eosinophil granulocytes. Treatment with chloramphenicol was stopped and cortisone was given, without effect. Without any further treatment the symptoms cleared, but the blood and bone-marrow pictures were still unaltered two months later.

The pattern of the toxic effect of chloramphenicol on the hæmopoietic tissues is one already familiar to us from the toxic effects of sulphonamides. These effects may appear quite quickly after a small dose in people whose blood-forming tissues are presumably exceptionally susceptible to the drug, or else after long-continued dosage when toxicity is more severe; reported deaths have, so far, been limited to this group. Now that we know that chloramphenicol may affect the blood-forming tissues, certain precautions should obviously be taken. Experience with many drugs that cause agranulocytosis has taught us that the onset of granulocytopenia is often so rapid that even regular blood-counts give us no warning; but if chloramphenicol is used for a long course of treatment, it would be sensible to have weekly blood-counts done. Any symptom suggesting affection of the blood-forming tissues—such as hæmorrhage from the nose or other mucous membranes, an unusually heavy menstrual loss, an unexplained sore throat, or purpura—should be the signal for discontinuing the drug and examining the blood. The experience of Wilson et al. suggests, too, that treatment with chloramphenicol should not be resumed in such patients.

DANGER FROM DRIED CULTURES AND VACCINES?

DRIED therapeutic products, such as antibiotics, are obviously free from serious risk to those who make and use them, though they may occasionally cause unpleasant effects.[1] But what of dried cultures and vaccines? In laboratories a rumour has been circulating that one worker contracted enteric fever by inhaling particles from a dried culture.

The risk is, of course, well known; and fluorescent tracers have been used to estimate the danger of airborne spread of the light particles of such dried material.[2] Fortunately the risk can be largely overcome by inserting a cotton-wool plug in the neck of an ampoule before it is sealed. Such a plug, however, can itself be a source of danger; for it is likely to contain fine particles of the dried material, and when it is grasped these particles may be diffused on to the skin or into the air. It is essential, therefore, that the plug should not be touched by the hand and that on withdrawal it should immediately be discarded into a container that can be sterilised.

[2] Cowan, S. T. *In* Freezing and Drying. London, 1952; p. 127.

Living vaccines are used widely in veterinary practice and occasionally in human medicine. The organisms are non-pathogenic variants, which are presumably harmless; but there are technical problems in manufacture. During vacuum-drying, material may escape from the ampoules and reach the interior of the vacuum system; gales of 800 miles per hour occur in an efficient machine,[3] and cross-infection of ampoules is possible when two or more cultures are dried at the same time. Drying plants cannot be satisfactorily sterilised, and therefore the same machine cannot safely be used to dry two types of organism, even at different times.

STRUCTURE OF GROUND SUBSTANCE

To the naked eye interstitial connective tissue has a membranous appearance, but under the microscope this is replaced by a picture of a network of fibres, with occasional cells. In the last twenty years the nature of the apparently structureless mesenchymal ground substance lying between these collagen fibrils has been elucidated by numerous studies centring around the admirable work of Duran-Reynals[4] Meyer et al,[5] and Chain and Duthie[6] on spreading factors and mesodermal polysaccharides. The work of Hechter[7] has underlined the importance of the mechanical factors of pressure (e.g., œdema) and volume in determining hyaluronidase spreading action, but little attention has been paid to the structural aspects of the interfibrillary substance which may influence these factors. During the last five years Day[8] has presented a convincing structural conception of the ground substance, illustrated by simple and compelling experiments, which does much to explain both the membranous quality and the especial permeability of connective tissue.

In 1876 Flemming[9] described cementing substance in and around the fibre-bundles of connective tissue, and noted that weak acid caused coagulation and contraction of this substance, whereas the collagen fibres swelled. Day has re-stated and amplified this observation. He found that at about pH 4 lamellæ of connective tissue from rat fascia became opaque and shrunken, while increasing alkalinity caused increasing swelling; the collagen fibres themselves showed no microscopical change until the pH exceeded the range 4–11. The concentration of neutral salts causing swelling became proportionately less as the hydrogen ion concentration fell. In wet preparations of connective tissue he noted irreversible changes at a slightly more acid pH (3·6); the hitherto clear interfibrillary spaces became opaque under dark-ground illumination, owing to the appearance of exceedingly fine branching fibrils and refractile granules. 50–60% ethanol induced similar changes, and Day found the resulting microscopic appearance of a fine network lying in the same optical plane very strikingly similar to the membranous naked-eye appearance of connective tissue. The collagen and elastic fibres were embedded in the opaque membrane "like twigs in a frozen pond." Trypsin treatment disintegrated this membrane, but hyaluronidase left it structurally intact. Day concluded from this and other work on the hydration of connective tissue, that a main constituent of the interfibrillary substance was of a protein nature, precipitable at its isoelectric point, organised in structure, and not leached out by water.

Contemporary workers have been much preoccupied with the mucopolysaccharides in ground substance; and, while opinions have differed as to whether they are free or bound to the protein element, no clear picture has hitherto emerged of how the interfibrillary substance is organised within the meshes (often 50 μ or more across) of the fibril network. In electron micrographs, although the collagen structure is revealed with great clarity the ground substance remains amorphous.[10] More recently Day[11] has described experiments in which he measured the rate of flow of saline across a mouse-connective-tissue membrane occluding the end of a vertical tube immersed in saline. Hyaluronidase added to the perfusing fluid increased the rate of flow 10–20 times. Subsequent perfusion of starch solution reversed this effect, while the effect of ptyalin on the starch-perfused membrane mimicked that of hyaluronidase on untreated membrane. Histologically, iodine treatment of the starch-perfused membrane showed homogeneous blue staining extending across the interfibrillary spaces. The starch was not removed by prolonged subsequent re-perfusion with saline. Day established that these findings were not due to a mere viscosity effect of macromolecular substances; and he attributes them to a sieve-like action of the permanent protein trellis of ground substance which he previously described. He concludes that the structure of the interfibrillary substance is that of an organised protein network, whose meshes are "water-proofed" by molecules of polysaccharides susceptible to the action of hyaluronidase.

P.I.E. OR P.U.O.?

TWENTY years have passed since Loeffler[12] first described a symptom-complex comprising transient pulmonary infiltrations and eosinophil leucocytosis in the blood. His cases ran a brief and benign course, and in a high proportion there was a history of diseases of allergy. Since then many similar cases have been described, but in some the patients have been ill longer and more seriously. Reeder and Goodrich[13] suggest that the classical syndrome represents the benign end of a range of disorders extending by degrees to severe and irreversible disease, as in periarteritis nodosa. They propose the introduction of a new term—"P.I.E. syndrome" to denote pulmonary infiltration with eosinophilia.

Ruzic et al.[14] feel that Loeffler's syndrome should be understood to include transient infiltrations in other organs. They report a case with asthmatic symptoms, vomiting, and abdominal pain in which transient pulmonary shadows and blood and marrow eosinophilia were found. The abdominal symptoms led to suspicion of gastric carcinoma, but gastrotomy showed a purely submucosal mass lying along the lesser curve. Biopsy showed an inflammatory infiltrate containing a fairly large number of eosinophils. The mass resolved spontaneously within two months. Loeffler's syndrome has also been described in conjunction with eosinophilic infiltrations of lymph-glands, muscle, and epididymis,[15] and inflammation of serous membranes.[16] Lyon and Kleinhaus[17] reported this syndrome associated with skin eruptions resembling erythema multiforme, but unfortunately no biopsies were done. More recently, Argentinian workers[18] have described an erysipeloid-like skin lesion with blood eosinophilia and fleeting infiltrations of the lungs in a case of lymphoid leukæmia after treatment with urethane. Skin biopsy showed an infiltrate which, in the subcutaneous layers and the fat, contained numerous eosinophils. "Eosinophilic granuloma of the skin" is not an entity, but at least some of the lesions described under that name are probably allergic in origin. Lewis and Cormia[19] reported a case associated with tinea pedis: the lesions were aggravated by injection of trichophytin, and similar patches appeared where the injections were made. This resembles the experience of Dostrowsky and Sagher,[20] who described positive reactions to the antigen of *Dirofilaria immitis* in cases of "eosinophilic erythrœdema" of the skin, with in three instances recrudescence of the skin lesions. It would be interesting if Leoffler's syndrome could be shown to be present in endocarditis parietalis fibroplastica, where eosinophilia and residence in the tropics raises the suspicion of allergy to parasites—e.g., loa loa.[21]

How pertinent is the eosinophilia in these cases? Over-emphasis on its importance has led to grouping of quite dissimilar lesions—e.g., the eosinophilic granulomas of the skin. We do not know the function of the eosinophil leucocyte; but clearly an allergic reaction is only one of many processes that can evoke eosinophilia, just as allergy is only one cause of fibrinoid degeneration. Perhaps we are dazzled by these mysterious beauties, whose presence may be more ornamental than significant. Several notable histopathologists are colour-blind.

TUBERCULOSIS IN THE COMMONWEALTH

THE third Commonwealth Health and Tuberculosis Conference of the National Association for the Prevention of Tuberculosis (N.A.P.T.), held in London this month, has brought visitors and views from many parts of the world. Representatives from Mauritius, Singapore, British Guiana, and the Colonial African Territories reported great advances in the use of tuberculin-testing and X-ray surveys to measure infectivity and find new cases. Africans, it seems, cannot stomach bed rest or isolation in hospital; but chemotherapy has given us the means to combat their diseases in spite of these prejudices, and fortunately results are as good with them as with white men. Moreover the old notion that Africans and Asians cannot withstand tuberculosis appears to be ill founded; or perhaps their resistance is improving. At all events speakers from many tropical regions agreed that, provided the environment was satisfactory, their patients resisted well enough. B.C.G. vaccination is now widely used, and plans are on foot in Jamaica and Trinidad to immunise all susceptible children within the next two years. An annual X-ray examination is proposed for the 300,000 African miners of the Witwatersrand gold mines, among whom an incidence of 4 active cases of tuberculosis per 1000 radiographed has already been found. India has already made history with a record of 8 million people tuberculin-tested and $2^1/_2$ million vaccinated with B.C.G.—yet this is a mere beginning in that vast population of 356 million. Pakistan, estimated to have 2 million cases, is mainly agricultural, and has meagre resources to deal with its problem. Progress is slow and at present depends largely on the help of the World Health Organisation. This may be contrasted with the enviable position of Canada, where there are 18,000 sanatorium beds—a ratio of 5 beds to 1 annual death from tuberculosis. There Koch's bacillus is pursued in mobile mass X-ray units of the bus type, augmented by equipment carried in railway coaches.

News of isoniazid was much the same as we have had already from the British Tuberculosis Association,[22] but Prof. Ralph Tomsett, from the Cornell Medical centre, warned his hearers against the possibility of florid fatal relapses in patients who have developed resistant mutants.

At a joint meeting of the N.A.P.T. with the B.T.A. to discuss childbearing and tuberculosis, Dr. C. J. Stewart surprised some of his hearers by concluding that whether the disease is minimal, moderately advanced, far advanced, or quiescent, its progress is uninfluenced by pregnancy, parturition, or the puerperium. He based this opinion on the five years' after-history of a large series of lung cases, comparing it with a control group who were not pregnant. He averred, too, that there are no medical indications for terminating pregnancy on account of tuberculosis. Nevertheless he counselled against a woman with active or unstable disease having a baby within two years of quiescence, and held of course that a mother with active disease should not breast-feed her baby (who, incidentally, should be vaccinated with B.C.G.). Dr. Raymond C. Cohen confirmed these main conclusions from a study of 400 mothers in his own maternity unit at Black Notley Sanatorium, and emphasised the need to avoid hæmorrhages and fatigue during labour in the more anæmic tuberculous women. He suspends pneumoperitoneum refills for two months before the confinement, and counsels against resuming them too soon afterwards. In all acute cases, he thinks, lactation should be suppressed by the use of concentrated œstrogens. Dr. Geoffrey Beven, however, reported enlargement of cavities in 17 out of 41 puerperal cases, and moreover, in a group of 150 women sputum-negative before pregnancy, he had seen 10 become sputum-positive after delivery. Mr. Camac Wilkinson drew attention to the spontaneous improvement often seen, during pregnancy, in patches of cutaneous lupus, with relapse after childbirth. This, he suggested, might be due to the temporary increase in plasma sterols during pregnancy. A useful suggestion for case-finding was made by Dr. Cohen: if all pregnant women were given a routine X-ray examination of the chest, he said, we might expect to find 4 or 5 cases of pulmonary tuberculosis in every 1000, and hence some 3000 new cases in England and Wales each year.

The social aspects of the disease are changing with the change in methods of treatment. The Australian government have introduced a scheme by which the unfit tuberculous worker, if a married man, can be paid £8 5*s*. a week, and may also retain £4 a week additional income from other sources. Our own scales, of course, fall short of this. Our tuberculous patients are not housed as well as they should be. Dr. W. Hartston mentioned that while only 3% of all London's families, and 5% of its tuberculous adults, are believed to live under conditions of overcrowding, as defined in the Housing Act of 1936, yet barely half of the 30,000 tuberculous adults in the metropolis have a bedroom to themselves. Priority is given to tuberculous London families for rehousing outside the county; but this has caused some misgivings because the proportion of tuberculous in the rehoused communities may sometimes be as much as 3 or 4 times the proportion in London as a whole. Dr. Hartston, however, has found an incidence of new cases, in these rehoused communities, of only about a third of what might reasonably have been expected from the numerical prevalence. This applies not only to the tuberculous families but also to their neighbours. Nor has he been able to find evidence of an increased incidence among the—often rural—populations of the districts where the new estates are established.

ON July 14 Lord Tedder opened the International Congress of Physical Medicine which is being held in London this week under the presidency of Lord Horder. Mr. Iain Macleod, the Minister of Health, welcomed the delegates, who have come from 23 countries.

Public Health

PEOPLE, JOBS, AND HOUSES

New light on the social structure of Britain

B. Benjamin
B.Sc. Lond., F.I.A.
STATISTICIAN, GENERAL REGISTER OFFICE

THE volume of advance tabulations of the results of the 1951 Census in Great Britain,[1] published last week, is of considerable importance to medicine. The structure of the population in age and in its manifold social characteristics, such as occupation, are essential ingredients of the vital statistics to which medical officers of health turn for measurement of trends in public health. To clinicians population statistics may have a less immediate appeal. A new influence has been at work, however; for the tendency is, more and more, to contemplate the patient as a member of a community. The smallest unit of this is the family; at a higher level are the workshop or factory group, and ultimately the population at large. Close statistical study of the population is being taken up as a tool in the elucidation of the ætiology of disease. The approach to disease is now macroscopic no less than microscopic; and thus the contributions of human diathesis and environmental influences can be distinguished.

TABLE I—ENGLAND AND WALES: AGE AND SEX DISTRIBUTION IN 1931 AND 1951
(Numbers in thousands)

Age (yr.)	1931				1951			
	Male		Female		Male		Female	
	No.	%	No.	%	No.	%	No.	%
0–4	1510	7·9	1480	7·1	1896	9·1	1823	8·0
5–14	3298	17·2	3232	15·5	3065	14·6	2949	13·0
15–34	6471	33·8	6870	33·0	5850	27·9	6087	26·7
35–64	6581	34·4	7547	36·3	8211	39·1	9075	39·9
65 and over	1273	6·7	1690	8·1	1957	9·3	2832	12·4
Total	19,133	100·0	20,819	100·0	20,979	100·0	22,766	100·0

A first requirement in all these studies is a classified enumeration of the population. Apart from specialised and local surveys, this is obtainable only from a national census. Though power was given in the Census Act of 1920 to conduct enumerations more often, no intercensal interval has yet been less than 10 years and the census of 1951 was divided from the preceding enumeration by a long space of twenty turbulent years with only the national registration of 1939 as a stop-gap. The 1951 tabulations have therefore been eagerly awaited. This time the normal interval of several years between the date of the census and the publication of the results has been shortened to just over one year by taking a 1% sample of the records for advance analysis, leaving the full results to be obtained later from the whole body of records. The census tables cover the whole of Great Britain; but the figures cited here relate to England and Wales only.

The Ageing Population

The decline in the birth-rate since the latter part of the 19th century and the increased longevity brought about mainly by the conquest of the infections formerly causing tragic waste of life in infancy and youth have increased the proportion of people with degenerative disease and infirmity of old age. The general death-rate, even when analysed by cause, tells us little about this since it is an average of the mortality at all ages. When the effect of the higher fertility of earlier years in inflating the present middle age-groups is worn out by the passage of time, and the bulge in the age pyramid of the population has passed up to older ages, then we may expect the general death-rate, which has been falling, to rise again. Meanwhile we look to death-rates in narrow age-groups, and here in the census tabulations we have a precise measure of the denominators for present use and as a new base-line for estimations in the years until the next census. How do the new figures compare with those of 1931? How far has the ageing progressed? The figures are shown in table I.

The population of young adult men (15–34) has fallen from 33·8% of all men to 27·9%. The percentage of all men over the age of 65 has increased from 6·7 to 9·3. For women the percentage in the 15–34 age-group has fallen from 33·0 to 26·7, while at ages over 65 the proportion has risen from 8·1 to 12·4. The improved survival of women (not only an absolute improvement but also an improvement relative to that of men) has accentuated the old-age weighting of their population structure. The effect of the temporary post-war boom in births can be seen at ages 0–4.

The need for attention to age-distribution is further illustrated in table II, showing the changing pattern of mortality from age to age.

Sex Differences in Disease

Apart from the obvious differences in the occupational risks as between the two sexes, giving rise to differing morbidity experience, and the special risks of women in pregnancy and childbirth, there is evidence of consti-

TABLE II—PRINCIPAL CAUSES OF DEATH IN AGE-GROUPS: ENGLAND AND WALES 1948–49

Age-group (yr.)	Cause of death	5th Revision International List	Deaths	Death-rate
				Per 1000 related births:
Under 1	Congenital malformations Birth injury, and Other diseases of early infancy	157 158 160, 161	17,859	11·79
	Prematurity	159	12,081	8·00
	Respiratory diseases	104–114	9542	6·17

TABLE III—RATIO OF FEMALE TO MALE DEATH-RATES (ALL AGES): ENGLAND AND WALES, 1949

Cause of death	International List	Death-rate per million		Ratio F : M
		Males	Females	
Cancer	45–55	1981	1771	0·89
Diabetes	61	54	104	1·93
Respiratory diseases ..	104–114	1635	1095	0·67
Peptic ulcer	117	185	50	0·27
Disease of gall-bladder ..	126,127	20	48	2·40

tutional (as distinct from environmental) causes of variation in susceptibility to certain diseases. Table III illustrates the type of variation.

The ratios fluctuate from disease to disease even more violently when narrow age-ranges are taken. Martin (1951) has drawn attention to the faster decline in mortality in females compared with that in males during the past hundred years; he finds that it is difficult to separate the effects of social class or occupation from other factors.

Clearly, then, there will be considerable interest in the sex ratios in the general population, since these are likely to influence the total volume of disease. The changes since 1931 are indicated in table IV.

At very young ages the higher (male to female) sex ratios at birth in war and post-war years have slightly increased the male superiority in numbers. At middle ages males are less deficient in numbers relative to females than formerly. At ages over 65 the still further relative improvement in the longevity of women gives them an enormous numerical advantage—much greater still than in 1931. The medical effects of this change are reflected in health service statistics. Of all cases, other than pregnancy and childbirth, discharged from hospitals covered by the General Register Office survey in 1949 (Mackay 1951) 10·4% were females aged 55 and over, compared with 11·6% of males in this age-group. Of all cases nursed at home by the L.C.C. home nursing service in 1950 (Benjamin and MacGregor 1950), however, 32·5% were females over the age of 60, and only 15·8% were males over 60. The effect is therefore mainly on the volume of chronic sickness which is nursed at home and is not treated in hospital.

Marriage

There was a tendency during and after the war of 1939–45 for spinsters to marry earlier, thus tending to increase the average period of exposure of married women to the risk of childbearing and bringing to the care of antenatal clinics, maternity departments, or domiciliary midwives, mothers of a younger average age. In addition we have the effect of the higher marriage-rates in the early years of the late war and after. (Some of these were not extra marriages but marriages which, if there had been no war, would have occurred sooner or later; the war merely affected their timing.) In this context it is only necessary to look at the proportion married at younger ages to see that there have been large changes; at 25–34, for example, the proportion has risen from 67·0 to 81·9% (see table V).

TABLE IV—SEX RATIOS IN THE POPULATION OF ENGLAND AND WALES

Age (yr.)	Sex ratio (i.e., females per 1000 males living in each age-group)	
	1931	1951
0–4	980	961
5–14	980	962
15–34	1062	1041
35–64	1147	1105
65 and over ..	1328	1447
Total	1088	1085

The proportion of women who are married is of interest, too, in any general measure of morbidity, since often marriage means the removal of a woman from the environment of the office, shop, or factory to the environment of the home where the stresses and strains are different. The bearing of this factor on, for example, the shape of the age-curve of tuberculosis mortality in women has seemed important in the light of evidence of higher morbidity in those who married and remained at work (Benjamin and Nash 1950), though a more important factor may be the more acute form of the disease in females (Springett 1952).

Occupation and Social Class

The importance in the ætiology of disease of nutrition, cleanliness, fresh air, the comforts of living, congenial employment, and all the intuitively recognised but vaguely defined elements which make up that complex connoted by "social conditions" has already been cited as a reason for expecting heightened medical interest in the results of the census. In addition there is the demand for more up-to-date information for the continuing and more intensified studies of direct occupational hazard. Much work has been done in recent years perforce on the basis of 1931 figures of occupational and social class-distribution, though it has been realised that since that year the preparation for war and the rehabilitation of the national economy in peace have possibly involved profound disturbance of the industrial and occupational distribution of man-power.

TABLE V—PROPORTION OF WOMEN MARRIED: ENGLAND AND WALES

Age (yr.)	Proportion of women ever married (*% of all women*)	
	1931	1951
15–19	1·8	4·5
20–24	25·8	48·4
25–34	67·0	81·9
35–44	80·6	86·6

In looking at table VI two important changes must be borne in mind: (1) 1931 was a year of economic depression and heavy unemployment, and men may have recorded occupations representing not their normal skill and practice but temporary employment governed by opportunity rather than choice; and (2) the school-leaving age has been raised and National Service instituted since 1931, resulting in later entry into trades and professions. Furthermore, changes in the occupational classification between 1931 and 1951 render it impossible to make precise comparisons without lengthy explanations. In table VI an attempt has been made to adapt the 1931 figures to the 1951 classification; the adaptation is approximate only, but the general nature of changes indicated may be accepted as reliable.

Thus comment on the 1951 figures shown in this table must necessarily be cautious. It does seem clear that the drift from agriculture, from village to town, may have continued. There are far fewer miners now than twenty years ago. Increases in the chemical and engineering occupations reflect the higher level of armament production, as well as the export drive in motor-cars and other post-war needs for machinery. There are fewer textile workers but more builders; more clerks and fewer women in domestic service; more professional workers (and some new professions); many more soldiers, sailors, and airmen.

The effect of these changes of occupation on the social-class gradient is indicated in table VII for men aged 20–64. A personal impression is that the change, though significant, is slight and amounts to a small general shift upward, mostly from unskilled workers to skilled workers. (Doubtless *within* social classes there have been changes in distribution, as is evidenced in table vi; and there have also been small changes in the actual classification, which have been ignored.) If this observation appears out of accord with common impressions based on contemporary income-levels, it must be remembered that the allocation of occupation to social class is related not solely to current income but to a broader view of the general standing of the occupation in the community. For this reason some occupations occupy a higher social class than other occupations with larger incomes. The various elements of the social complex to which reference has been made are closely correlated, though perhaps less than formerly; income and housing and education are still dependent on each other, and it is impossible to separate their effect on health. Indeed, if this were not so the composite measure of social class would not be needed, for direct association with more objective variables would be preferred.

In the London boroughs in 1931–33 (Benjamin 1952) the mortality-rate from pulmonary tuberculosis was correlated with the percentage of the borough population in social classes iv and v (coefficient of correlation +·73) and with the percentage living at a density of more than 1½ persons per room (+·69); but social class and housing density were correlated (+·72); and while the partial coefficient of correlation of tuberculosis mortality with social class (holding the housing effect constant) was +·45, the correlation with housing (holding social class constant) was slightly less at +·35.

In the circumstances, and for medical purposes, the social-class grading is probably as realistic a measure as any of the environmental and educational influences as a whole. (Those who are unfamiliar with the grading will find details in the Classification of Occupations 1950 (General Register Office 1951). The social-class allocations are also shown in table ii. 1 of the 1% sample.)

TABLE VI—OCCUPATIONS OF MALES AND FEMALES IN 1931 AND 1951: ENGLAND AND WALES
(Numbers in thousands)

Occupations	Males 1931 (14 +)	Males 1951 (15 +)	Females 1931 (14 +)	Females 1951 (15 +)
Fisherman	27	17	—	—

Total	14,633	16,019	16,411	17,993

TABLE VII—SOCIAL CLASS IN MALES AGE 20–64: ENGLAND AND WALES
(Numbers in thousands)

Social class	1931		1951	
	No.	%	No.	%
I. Professional and managerial	278	2·4	432	3·4
II. Intermediate between I and III	1569	13·8	1939	15·2
III. Skilled workers ..	5499	48·5	6609	51·9
IV. Intermediate between III and V	1993	17·6	2004	15·7
V. Unskilled workers ..	1845	16·3	1572	12·3
Unoccupied *	158	1·4	190	1·5
Total	11,342	100·0	12,746	100·0

* These are not normally gainfully employed; this group does *not* include those workers who were, at the census, unemployed and who are classed to their customary occupation.

Of the many diseases in which social-class gradients of mortality are striking, coronary heart-disease, owing to the heavy increase in deaths assigned to it, has been the subject of much discussion (Morris 1951, Logan 1952). In giving advance social-class allocations for deaths in 1949 from heart-disease Logan was justified in what was then an assumption—that the social-class distribution of the population exposed to risk had not suffered sufficiently large changes since 1931 to invalidate his comparisons. It appears therefore that the social-class gradient of coronary disease (formerly decreasing from i to v) has in fact become less evident, though the opposite gradient of myocardial disease has been maintained. Peptic ulcer is another disease in relation to which social class is important. Comment has been made (Benjamin 1949) on the variation of the relationship between gastric and duodenal ulcer with social grading. Within the peptic-ulcer group of deaths gastric ulcers become more preponderant with descent in the social scale. The suggestion is that the type of mental distress and intensity of living associated with duodenal ulcer is more within the experience of higher "social classes," while it is in the lower "social classes" that there is more likelihood of feeding habits which produce injury of the gastric mucosa associated with gastric, as distinct from duodenal, ulcer (Nicol 1941).

Housing

In 1951 the proportion of structurally separate dwellings in England and Wales shared by more than one household was 7·0%, compared with 9·1% in 1931. In terms of families 15% of private households were sharing occupation of a dwelling in 1951 compared with 19% in 1931. For epidemiologists this is an important fact, for households in shared occupation may maintain an economic independence but are bound to be in more frequent contact with each other than if each occupied structurally separate dwellings. It has been shown (Stein 1952) that in Glasgow tuberculosis mortality is more highly correlated with persons per dwelling than with persons per room—i.e., the total number exposed to risk in the small community of households in the dwelling may be more important than their actual density of occupation.

It is doubtful whether anyone has ever separated the effect of housing on health or even satisfactorily defined what is meant by "housing effect." Correlation of disease incidence may merely reflect correlation with income, as has been illustrated already. If a tuberculous person has to share a bedroom with a non-tuberculous contact, that would probably be regarded as a real effect of overcrowding on health. A Bristol investigation suggested a relationship between basement rooms and rheumatic fever (Daniel 1942), but it was not statistically significant; and other stronger relationships with social factors were operating. Dampness, lack of fresh air, lack of light, or lack of warmth must all take their toll; but it would be difficult to carry out controlled experiments to measure the precise effects. Housing conditions cannot be interfered with for the sake of experiment.

Persons per household in England and Wales decreased from 3·72 in 1931 to 3·19 in 1951—a product of the recent high marriage-rates and also of a significant rise in "one-person" households. There has been, too, a very large rise in the number of dwellings from 9,123,000 in 1931 to 11,934,000 in 1952. Persons per room fell from 0·83 to 0·73, and the percentage of persons living in overcrowded conditions (more than 2 per room) fell from 6·94 to 2·16. The average housing density of 1951 is not as bad as in 1931, however many people may still be waiting for better accommodation. The figures will of course repay more detailed examination. For example, for families of the same size the average number of rooms available is the same in 1951 as in 1931 and the improvement in density seems to arise from an increase in small households with low density and a reduction in large households with high density.

Household Arrangements

While there has been a considerable reduction in the mortality from—and indeed in the incidence of—enteritis and diarrhœa, notified cases of dysentery have been more frequent in recent years. This increase is not entirely confined to institutional outbreaks; nor is it wholly due to improved pathological services and better diagnosis. Food-poisoning has become so much more prevalent, and has aroused so much more public concern, as to have been included among the notifiable diseases. This greater prevalence is symptomatic of an era of extended resort to communal feeding, but the handling of food in private homes often leaves something to be desired. The development of detergents may have outpaced improvement in personal habits. There is still need to remind ourselves of the simple truths of hygiene which our forefathers learned only from the tragedies of cholera and other pestilences. Much depends, however, on the means of cleanliness. The results of the census indicate that out of 13,043,500 households in England and Wales 5,817,400 (44·6%) are without exclusive use of a fixed bath (1,008,200 households are sharing a bath and 4,809,200 households are entirely without a fixed bath)—i.e., it is not easy for these households to take a bath, though presumably most have portable baths and access to public baths. There are 21·4% of households without exclusive use of water-closets (7·9% entirely without). There are 13·8% of households without exclusive use of both sink and stove (6·3% are entirely without a kitchen sink). There are 1,541,900 households sharing a piped water-supply within the house and 735,400 entirely without, making a total percentage of 17·5 without exclusive use of piped water in the house.

Such figures provide essential comparative information when local epidemiological inquiries involving these factors are carried out. It is not enough to know the facilities available to those in whom disease is observed; it is equally important to know as much about those who have escaped. One example is recent study of enteritis in the London area in which factors of cleanliness were recorded.

Paratyphoid-B Fever in Cardiff

An outbreak of paratyphoid-B infection occurred at Cardiff in 1939, and since then there have been sporadic infections at the rate of one or two cases each year.

An outbreak began on May 6 this year when a Cardiff resident, who was employed outside the city in one of the coal-mining areas, sickened. He was not notified as a case of paratyphoid-B fever until May 23, some 17 days after his first symptoms. Dr. W. Powell Phillips, the deputy medical officer of health, to whom we are indebted for these notes, says that by this time it was known that other cases of paratyphoid fever were occurring in the mining district where he was employed and where he had food in the daytime. The onset of these cases coincided with the Cardiff case.

The next patient—an infant, aged 10 months—sickened on May 10. This case was notified on May 17. With such a small child and the restricted dietary it was possible to pin-point the likely source of infection, and it was found that the child had been given some cream trifle. This was also taken by 3 adults and 1 other child, aged 3 years, in the family. On routine investigation it was found that they were excreting paratyphoid-B bacillus, type I. The child aged 3 sickened on May 28, but the adults remained symptomless excretors. The cream trifles were manufactured outside Cardiff, and investigations at the source of supply provided no clue to the infection.

A further case was notified on June 6; this was in a woman who had been ill for 10 days before notification. Synthetic cream confectionery was the most suspicious article of food and in 14 subsequent cases the same kind of food came under suspicion. This was traced back to a large confectionery establishment, and on routine fæcal investigations it was found that there was an excretor among the staff. This excretor also had mild symptoms, and as the agglutination titre rose considerably it is considered that he was a case rather than a symptomless carrier. There is absolutely no evidence to link these cases with the first cases notified in Cardiff, although every effort was made to detect a common source of infection. A further 8 cases have been notified in Cardiff, and again the most suspicious article of diet has been cream confectionery; but the source of supply has not, so far as can be ascertained, been common manufacturing or sales establishments.

An interesting feature of this outbreak has been that there have been some 100 cases of paratyphoid-B, type I, infection within a radius of about 50 miles, mainly in the mining valleys which radiate from Cardiff. Confectionery seems to have played a prominent part in the history of most of the cases, and many bakeries have come into the picture. A detailed study of the commodities used in the industry has revealed how intricate are the sources of supply for the various articles which go to make up modern confectionery. The primary manufacture of these products, such as synthetic cream, dried egg, and liquid egg, is outside the Cardiff area, and they have a nation-wide distribution. Viewing this epidemic as a whole, it seems that some wholesale establishment supplying bakeries in this area may be a source of infection. Furthermore, Cardiff serves as a distribution centre for the greater part of the area in which cases have occurred.

Bacteriological investigations have been carried out on the staff of such suppliers and also on samples of synthetic creams, dried egg-white, frozen egg, custard-powders, pastry and cake margarines, and marshmallow, with negative results so far.

Most of the patients have not been severely ill, but among the 25 cases up to July 2 there have been 2 deaths. It is noteworthy that in 2 cases the organism was isolated from the fæces 24 hours before symptoms developed.

The Public Health Laboratory Service has been responsible for the enormous amount of bacteriological investigations involved, and they have also been advising on, and taking part in, the epidemiological investigations. The Welsh Board of Health has been actively engaged in coordinating the investigations throughout the whole affected area.

BRITISH MEDICAL ASSOCIATION

The joint annual meeting of the British Medical Association and the Irish Medical Association was concluded in Dublin last week. Three plenary scientific sessions were held, and the various scientific sections met during the second half of the week.

The annual dinner of the two associations was held in the Pavilion of the Royal Dublin Society on July 10. The minister for health of Ireland, Dr. James Ryan, proposed the toast of the associations. He forecast an extension of the health services in Ireland in the near future, but he would not be drawn into any details. He did, however, declare that whatever was done would be based on "the solid foundation that has stood the test of time—the family doctor." Dr. E. A. Gregg responded for the B.M.A. and Prof. T. G. Moorhead for the I.M.A. Professor Moorhead thought that the medical schools were turning out too many doctors. Their energies would be better concentrated on turning out really healthy patients suitable for the lists of doctors practising under a national health service. The Guests was proposed by Dr. I. D. Grant who hoped that the lessons learnt from the National Health Service would be of value to those who were planning the medical affairs of Ireland. Senator Andrew Clarkin (lord mayor of Dublin), Dr. P. P. Lynch (New Zealand), and Prof. E. Grzegorzewski (World Health Organisation) replied. Mr. T. C. J. O'Connell proposed the toast of the new President of the B.M.A., Dr. P. T. J. O'Farrell, who, he said, had done so much to build up the I.M.A. into a strong and representative body. Dr. O'Farrell made a brief reply.

On July 10 Dublin University conferred honorary degrees on Dr. H. A. Clegg, editor of the *British Medical Journal*, Dr. Gregg, chairman of the council of the B.M.A., and Dr. O'Farrell. The honorary degrees conferred by the National University of Ireland are given on p. 151.

A scientific exhibition was arranged in University College. Here Prof. K. H. Digby demonstrated a new nasopharyngoscope for the early detection of carcinoma. A model of the nasopharynx was available for surgeons to try the instrument by identifying 'Plasticine' tumours and taking "specimens" for biopsy. Mr. O'Connell's exhibit illustrated the pathology and surgery of mitral stenosis, using specimens, models, and diagrams. A colour film of the operation of valvulotomy was shown. Dr. J. J. Stevenson illustrated the value of a new contrast medium for bronchography. This is an ester of diodone, suspended in water with carboxymethylcellulose. Its particular virtues are the ease and evenness of its spread through the bronchi and the absence of alveolar filling, which is uncommon even after coughing. It is much more rapidly absorbed than iodised oil and usually disappears in from one to four days. Dr. D. A. Darcy had brought a number of excellent enlargements of photomicrographs to show what happens after tissue transplantation. The histological disintegration of the homograft was contrasted with the successful consolidation of the autograft. The most interesting pictures were those of an adrenal-gland homograft which had apparently taken in a rabbit—an observation which may lead to a better understanding of grafting phenomena. There were 26 exhibits in all, and the exhibition's popularity was evident from the brisk business at every stand.

The manufacturers of 'Ethicon' sutures had arranged showings of a three-dimensional colour film made at the Lahey Clinic, Boston, Mass. Through polarising spectacles, the audience saw with remarkable clarity the operation of radical gastrectomy for carcinoma of the stomach. The depth of focus achieved was amazing, and the effect was like looking through a window directly on to the operating-table.

Plenary Sessions

THE RELIEF OF PAIN

Chairman : Dr. O. C. Carter

Prof. V. M. Synge (Dublin) introduced the subject with some general ideas about pain. He thought that most people fell into one of two groups: (1) those who recognised three types of pain—upper abdominal, lower abdominal, and extra-abdominal—for which the appropriate treatments were respectively bicarbonate of soda, salts, and aspirin with or without a rub; and (2) those to whom pain was more complex and its significance more alarming. We do not really know how pain is produced; for though the nervous pathways carrying pain sense can be traced readily enough to the thalamus, matters become confused and uncertain above that level. Visceral pain is particularly puzzling; it is satisfying to attribute the pain of a duodenal ulcer to the passage of acid over a raw surface, but that cannot be the complete explanation. Professor Synge hoped that the doctor who had never experienced real pain would be cautious in estimating the impact of pain on his patients. When no organic disease is found, the pain is all too often said to be imaginary or trivial. When a doctor says: "Your pain is only muscular," it is clear that the doctor has never had lumbago. *Dolor animi gravior est quam corporis*, he summed up, or, in other words, it is worse to give the patient a pain in the neck than to tread on his toe.

Dr. E. T. Freeman (Dublin) emphasised the physical deterioration which can result from unrelieved pain—e.g., in thrombo-angiitis obliterans. He thought that town-dwellers complained more readily of pain than country folk; one of the features of modern civilisation was the demand for the relief of the transient pain, a demand met by the enormous growth in popular analgesics containing what are almost homœopathic doses of codeine. Turning to pain as an aid to diagnosis, Dr. Freeman regretted that more attention was often focused on relieving a pain than on determining its cause. It could not be repeated too often that a pain should only be suppressed after the diagnosis had been made. Negative findings on clinical examination and on investigation were not conclusive. If the patient sensed that his pain was being underestimated, he often developed hysterical overlay in an attempt to convince the doctor of its reality, and he thus obscured still further its true physical basis. The ideal means of relieving chronic pain had not yet been achieved. A drug that will suppress pain without affecting consciousness or muscular power and without producing the euphoria that leads to addiction awaits discovery. Dr. Freeman was guarded in his estimate of surgery as a means of relieving pain. Was the patient with angina of effort any better off because his cardiac anoxæmia passed unnoticed? Leucotomy was of undoubted value in some cases, but if used unwisely it might be even more destructive to the patient's personality than morphine addiction.

Prof. D. M. Dunlop (Edinburgh) described the pharmacology and uses of the pain-killing drugs. He made a particular point about pethidine; it is insufficiently realised that this drug causes spasm of the sphincter of Oddi and, though it is useful in intestinal and ureteric colic, it should not be used in biliary colic. Pethidine has no action on the cough reflex, a property which recommends it for postoperative use, and little action on the respiratory centre, an advantage in obstetrical analgesia. Amidone has no effect on the sphincter of Oddi and is a good choice for biliary colic. Given intramuscularly, it is less nauseating than morphine, but given by mouth to ambulant patients it seems just as likely to cause vomiting. Professor Dunlop's recommendations in brief were:

In the late stages of hopeless disease: Heroin.

For pre-anæsthetic narcosis and for acute cardiac disease: Morphine.

For intestinal and ureteric colic, in obstetrics, and for postoperative pain: Pethidine.
For biliary colic: Amidone (intramuscularly).

He had found phenadoxone unreliable. In answer to a question, Professor Dunlop said that there was a strong case for stopping the legal use of heroin altogether, and thereby easing the task of those who are trying to stamp out its illegal production. Heroin addiction was not a serious matter in this country, but, in his own view, the dangers of its use outweighed the advantages. In another reply, he said that there was no evidence that injections of liver extract relieved the pain of herpes zoster.

Speaking about the surgical relief of pain, Sir GEOFFREY JEFFERSON, F.R.S. (Manchester), recalled a remark of Wilfred Trotter: "Pain is relievable in proportion to the presence of recognisable cause." When an inoperable cancer caused relentless pain by involvement of bone or nerve-plexuses, cordotomy or neurectomy could bring relief. When cordotomy failed to stop the pain, it did so, not because it was a bad operation, but because section of the cord had not been carried far enough. Recent work suggested that the spinal-cord pathways are arranged in laminæ, and to cut off all painful stimuli below a certain level it may be necessary to divide almost the whole of the anterior half of the cord. Cutting the posterior nerve-roots was useless in postherpetic neuralgia, for the virus often attacked the cord itself, as could be seen from the milky stains visible upon it at operation. He agreed with Dr. Freeman about the need for caution in advising leucotomy; he never pressed reluctant patients to undergo the operation. Asked if all forms of pain could be relieved surgically, Sir Geoffrey said that it was theoretically possible, but that theory could be defeated in practice. He had treated a man whose paralysed and painful arm had been amputated after a brachial-plexus injury. Phantom-limb pain was severe and cervical cordotomy was performed. The pain returned within 3 months, and finally the sensory cortex was exposed under local anæsthesia. The area corresponding to the pain was localised by electrical stimulation, and this area was then removed. The more agonising element of the pain was relieved, but some pain still persisted. It would be easy, said Sir Geoffrey, to say that this was an imaginary pain, but he thought that in cases like this there might be some unexplained spread of painful stimuli throughout the whole cortex. The destruction of nuclei in the thalamus was another line of attack, but results so far had not been as good as had been hoped.

Mr. F. N. REYNOLDS (London) considered that the methods of relieving pain in childbirth were unsatisfactory, especially in domiciliary midwifery. There were, he admitted, inherent difficulties in the way of providing the best method of analgesia for the mother in her home, but he thought that lack of interest and of determined exploration were contributing more to this unnecessary distress than any practical considerations. Midwives are often brought up to feel that the relief of pain is to be discouraged, and consequently those methods that were available were not used as fully as possible. The Minnitt apparatus was bulky and difficult to carry around, and the mother confined at home had usually to be content with a mild sedative. She was very lucky if she got gas and oxygen. Pethidine has made matters rather better, but there was still much to be done. We must give up the idea that the best midwifery is that of the midwife, Mr. Reynolds said. He appreciated and admired her work no less than anybody else, but his heart would fail him if he had to set out to a confinement as poorly equipped as she usually was. He suggested that an obstetrician or anæsthetist should be appointed in each district to advise midwives and mothers on methods of analgesia. This had been done in Hertfordshire with encouraging results. By this means he thought that a sense of coöperation could replace that of competition, and that the disinclination of the midwife to seek the doctor's advice could be overcome. He said that the 'Trilene' inhaler would probably provide the efficient and portable apparatus that was needed, but it had not yet been accepted as safe by the Central Midwives' Board. Many women did not realise that analgesia existed, and it was most important that prejudices should be discarded if all mothers were to be spared unnecessary distress. Mr. Reynolds was asked what could be done for the pain of severe dysmenorrhœa. He said that thyroid extract was the only drug offering hope of cure. Its effects were often good if it was started early enough—at 16 or 17. Otherwise medical treatment was palliative. The most stubborn cases usually improved after the first pregnancy.

Dr. S. WAND gave some reflections from the point of view of the general practitioner. He urged the necessity to regard all pain as organic until it had become reasonably certain that an organic cause had been eliminated, if necessary by more than one investigation. Much distress to patient and relatives and embarrassment to the doctor at the later discovery of such a cause could be avoided by this attitude. The elimination of anxiety, the doctor's encouragement, and his understanding of the patient and his background were important considerations in relieving distress. Talking of useful drugs, he said that he had found amidone to be the most effective drug for the relief of cough in pulmonary tuberculosis. Aspirin had lost favour as a gargle in the face of newer remedies, but he still thought it brought the quickest relief. Intravenous procaine might be more widely used by the practitioner—e.g., as an anæsthetic for the dressing of burns. He thought that pain-killing drugs administered by inhalation might be one of the advances of the near future that would improve our ways of relieving suffering.

DERANGEMENTS OF THE BODY-FLUIDS

Chairman: Prof. D. M. DUNLOP

Like the other plenary sessions, that devoted to Derangements of the Body-fluids was designed to give specialists an opportunity of presenting their case to the medical public, and of submitting to whatever questions might be asked. It is surprising how little attention one need pay to what constitutes the greater part of our bodies; and our mental aloofness can be condoned only by the efficiency with which our so-called lower centres order this matter for us. In disease, however, the wisdom of the body may fail, and the opening speakers addressed themselves to describing the consequent derangements of body-fluid, and the practical steps required to restore euhydria.

In his chairman's remarks, Professor DUNLOP, a veteran of the previous day's plenary session on the Relief of Pain, commended the subject, deplored its complexity, and promised to ensure that speakers kept within their allotted span—an instruction which was admirably honoured by those who spoke.

Dr. D. A. K. BLACK (Manchester) discussed some physiological principles underlying the distribution of body-fluid. It was possible experimentally to produce syndromes of water, sodium, and potassium deficiency, although in clinical practice these were often blended with one another and further confused by alterations in the acid-base balance. In the assessment of clinical derangement of body-fluid, the history and clinical examination gave information on the changes in volume of body-fluid. Biochemical estimations were of value in defining changes in the composition of body-fluid, and also in assessing the quantities of water and electrolyte required for repair of existing deficiencies. In treating dehydration it was important at an early stage to give sufficient saline fluid to restore any deficit in plasma volume; given a normal circulation to the kidneys, the patient was in a much better position to resist inappropriate fluid therapy This principle was illustrated in the treatment of diabetic coma, where the sodium and water deficit should be corrected early, and the concurrent potassium deficit could be left until later. On admission serum-potassium levels were often high, through concentration of the plasma and extracellular fluid volume; later, with adequate saline therapy the plasma volume increased and the potassium deficit could then be corrected without risk of inducing toxic effects due to a high serum-potassium.

Mr. A. W. Wilkinson (Edinburgh) gave a thoughtful and well-documented paper on the surgical aspects of body-fluid depletion. He described metabolic studies in the postoperative period, which showed that in addition to nitrogen-loss the organism laboured under some difficulty in disposing of administered salt and water. There was, however, a considerable loss of potassium, and this might be augmented by intestinal aspiration or by the injudicious administration of saline fluid. In fact, the majority of patients after operation did not require intravenous infusion, but when they showed clear symptoms of potassium depletion intravenous therapy, including potassium salts, was of great value. Mr. Wilkinson described the clinical syndrome of potassium deficiency, and showed a telling picture of a patient slumped in bed and patently careless of what was going on around her. Volume-for-volume replacement of fluid-loss by normal saline was inadequate, and might be dangerous; it was much better to use a replacement fluid whose ionic composition resembled that of the fluid which was being lost from the body.

Dr. S. P. Dundon (Dublin) then dealt with the important applications to pædiatrics of knowledge of electrolytes. The severe effects of dehydration on infants could be accounted for by the fact that fluid exchange in the infant was much more rapid than in the adult, so that an infant deprived of water would die twice as quickly as an adult. Infants had much more extracellular fluid in proportion to their body-weight, and somewhat less intracellular fluid. Normally, the infant's diet contained more water and electrolyte than was needed for its minimum requirement, so there was some reserve to deal with moderate abnormal fluid-loss, provided that intake was maintained. Serious dehydration could, however, come on rapidly if the fluid intake was interfered with, as often happened in gastro-intestinal disease. Treatment of dehydration was complicated by the less efficient regulation of electrolyte excretion by the infant kidney. The commonest cause of fluid depletion in infants was vomiting and diarrhœa. Usually dehydration in infants was fairly mild and could be treated by oral administration of dilute milk, with added sodium and potassium salts. Severe dehydration demanded parenteral treatment with dilute saline solution, either subcutaneously with hyaluronidase or intravenously. Dr. Dundon concluded with the aphorism of Talbot and Butler that "therapy must reflect common sense and careful clinical observation, and a tolerance indicative of an enlightened awareness of ignorance."

Dr. W. E. R. Hackett (Dublin) reminded the meeting that a symposium was literally a drinking together, and as his own contribution to this bottle-party he proposed a bottle of blood. He thought that analysis in the field of fluid therapy had perhaps run riot, and commended synthesis of the type achieved by Marriott in his Croonian lectures. Dr. Hackett went on to discuss wound shock, which he regarded as essentially related to blood-loss, for which rapid transfusion was a sovereign remedy. Following Grant and Reeve, he recommended as guides to the severity of blood-loss observations on the blood-pressure, pulse-rate, temperature, and facial colour. Even in syndromes of primary electrolyte depletion, it was important to correct anæmia, as defective blood-flow to the kidneys would greatly interfere with the correction of electrolyte imbalance. When anuria interrupted a transfusion, it was still important to correct anæmia with accurately matched blood.

During an interval, members had the opportunity of studying a comprehensive and effective demonstration arranged by Dr. Hackett on body-fluid depletion and replacement.

In the general discussion, Dr. Paul Fourman rescued the adrenal glands from the oblivion to which the opening speakers had unwittingly consigned them. He commented on the varying clinical pictures of potassium deficiency, and suggested that lack of potassium might account in part for the malaise of convalescence from operation or illness.

Mr. John Bruce (Edinburgh) expressed his pleasure at seeing a surgeon as one of the openers in a discussion on electrolytes. He emphasised the difficulty of picking the right time for operation in patients with pyloric stenosis or ulcerative colitis; and as a Parthian shot he exposed the ignorance of our profession on the real nature of "hepatic coma."

Dr. T. Parkinson (Luton) mentioned the value of electrocardiography in the clinical assessment of potassium deficiency. He pointed out how closely the apathy of potassium deficiency resembled neurasthenia, and he had seen symptoms attributed to neurosis disappear when the patient was treated with potassium.

Dr. W. N. Leak (Winsford) gently reminded members of the existence of the cell wall, suggesting that further work might be profitable on its relation to electrolyte exchanges.

Major-General J. C. A. Dowse described his tropical experience with heat exhaustion and cramps. He had found a mixture of gin, ginger-beer, and salt very useful in treating cramp.

Mr. Wilkinson and Dr. Black replied briefly to points raised in the discussion, and the meeting dispersed for fluid and electrolyte replacement.

DEATH IN EARLY ADULT LIFE

Chairman: Prof. J. McGrath

Dr. R. C. Geary (Dublin) said that the elimination of all but a few of the deaths at young adult ages was a reasonable objective of preventive and curative medicine; and the trend in death-rates of young adults in the European countries encouraged such a hope. In the past half-century the decline in death-rates ranged from 40% for Portugal to 78% for Norway; yet there was still a conspicuous difference between the countries of Europe, with Spain and Portugal showing young-adult mortality-rates more than twice those of the Scandinavian countries, the Netherlands, and England and Wales. The countries which started the century with the lowest death-rates had shown the biggest declines in mortality.

The secular trends in the tuberculosis death-rates had closely followed the general death-rates and there was a close correlation between the standard of living of a country and its tuberculosis death-rate for young adults. On the basis of national income, England and Wales and Ireland (the 26 counties) had more deaths from tuberculosis than they should have. Ireland showed up badly for deaths from non-respiratory tuberculosis, with a rate for this age-group of four or five times that for England and Wales.

Most countries, Dr. Geary said, had well-developed systems for analysing mortality-rates, but for those in the prime of life, morbidity statistics would be much more valuable as an indicator of medical and social problems. It was one of the iniquities of this time that undue emphasis was laid on problems which could be analysed statistically, whereas those with inadequate statistics, or none, were overlooked.

Dr. Ninian Falkiner (Dublin) quoted figures from the reports of the Rotunda Hospital. Between 1925 and 1937, he said, the maternal mortality was 6·2 per 1000, and in the period 1938–50 it had fallen to 2·8. Hyperemesis showed the most striking fall, from 0·29 per 1000 deliveries to 0·02. But the main improvement was due to the reduction in deaths from sepsis. Lives were still lost because adequate treatment was not readily available for difficult confinements. The death-rates from hæmorrhage and the late toxæmias were now the highest and more should be done to elucidate their causes. In comparing these two periods it could be said that deaths from cardiac disease as a complication of pregnancy had been reduced, but the mortality from tuberculosis had not changed.

Dr. Donald Teare (London) spoke as a pathologist who had since the war done more than 2000 necropsies on young adults—mostly coroners' cases and therefore highly selected material. But the outstanding feature in both men and women was the high number of suicides (183 men and 131 women), higher than any other single cause except coronary atheroma and hypertension. As a means of self-destruction, the most usual choice, for both sexes, was coal-gas poisoning; but men shot and hanged themselves more often than women, who chose the more dramatic methods of throwing themselves from buildings or under trains. The availability of coal gas played some part in its popularity, and a small number of these suicides seemed to be accidents in that the victims' intention was to excite sympathy rather than to destroy themselves. The inclusion of barbiturates on schedule IV of the Dangerous Drugs Act did not appear to have reduced the suicide-rate from this cause. Improved techniques in psychiatry and a more widely available mental-health service offered the best prospect of reducing these deaths.

Of the deaths from traffic accidents, 39 were motor-cyclists, of whom 30 died from fractures of the skull. Dr. Teare advocated legislation to make protective headgear for motor-cyclists compulsory. Another speaker, Major-General J. C. A. Dowse, suggested that crash-helmets should be sold as a necessary part of the motor-cycle.

Dr. Teare had had 44 cases where patients had died as the direct result of medical treatment. More than a third of these were due to air embolism, caused mainly by puncturing the lung with a needle during the treatment of tuberculosis. Drugs producing agranulocytosis were another potent cause of these misfortunes.* As soon as one drug fell into disuse because of its dangerous side-effects, another took its place and in time produced a further series of deaths. These deaths served to remind the medical profession of the need to review the value of certain types of treatment. He was horrified to read a recent article advocating puncture of the lung to induce pneumothorax. But with the great advances made in anæsthesia and surgery, there was not much difference for the general population, between the chances of being murdered and of dying under an anæsthetic.

Dr. Richard Schilling (Manchester) said that in the civilian population of England and Wales approximately 230,000 men and 223,000 women in this age-group died between 1940 and 1949; but only about 11,000 of these deaths could be ascribed to direct occupational causes such as accidents and industrial diseases. Most of these deaths were due to accidents, and though the general death-rates had declined in this period, the fatal-accident rate was the same now as it was before the war. Medical responsibility for preventing accidents extended beyond the limited scope of selection of workers and providing good early treatment in industry and hospitals. Doctors in industry could prevent biological stupidity in plant design and safety practices, and were in a favourable position to encourage industrial communities to take more interest in health and safety. In many different ways work undoubtedly influenced some of the common causes of death in this age-group—namely, respiratory tuberculosis, cardiovascular disease, and cancer. It was now recognised that factories could be a source of infection in tuberculosis, and the training of younger men with valvular heart-disease for suitable work could do much to prolong their lives. The death-rates for coronary disease were rising rapidly in the younger men, and the recent work by J. N. Morris and his associates had shown a high incidence of this disease in general practitioners compared with other doctors. There were probably occupational influences in its ætiology and it might be worth studying the histories of the younger men who suffered from it for clues to its social pathology. In the same way, the men who died early of cancer might give pointers to undetected carcinogens.

Industrial medicine was something more than a specialty dealing with industrial diseases. It was a discipline which took into consideration the many different ways in which work could influence health, and it could therefore help to elucidate the social causes of disease in individual patients and in groups.

Mr. Dickson Wright (London) said that the surgeon had done much to save life in young adults. The surgical treatment of acute appendicitis, perforated ulcers, and intestinal obstructions had become commonplace and successful, whereas not so many years ago 90% of sufferers perished. Those who died today did so from delay in diagnosis. The most usual mistake was to discount the patient's description of the pain, which after the first violent onset was followed by a lull. He strongly favoured resection in all cases of gastric ulcer because of the risks of malignancy, hæmorrhage, and perforation. While surgery had not yet provided any real help for coronary disease, there seemed good reason to hope that it might be possible to induce vascularisation by hormone therapy. Cerebral hæmorrhage, particularly from congenital aneurysms of the larger arteries of the base of the brain, was not uncommon in the younger people, and there was now no reason for depriving these cases of surgical help. He thought that not enough was done for head injuries. It was impossible for the cranial surgeon to look after them all. Some were left and died from failure to remove the hæmatomata which Dr. Teare found so often in the young men killed on the roads and elsewhere. He had in his lifetime saved ten patients who had attempted suicide. None had been reproachful of being saved, and some had subsequently lived very useful lives.

In reply to a question from Dr. Miller, Mr. Dickson Wright said that the American practice of reopening the abdomen at six-monthly intervals to look for recurrences of malignant disease after surgical treatment had not yet, as far as he knew, reached these islands.

Prof. Leonard Abrahamson (Dublin) said that not many years ago this discussion would have been largely concerned with puerperal and postoperative sepsis, acute generalised tuberculosis, and bacterial endocarditis. The advent of the antibiotics had changed the picture, and the optimism of Dr. Geary for the future rested on recent achievements.

In his experience in Ireland there had been a curious change in the symptomatology of rheumatic carditis, which was responsible for many of the deaths in early adult life. Rheumatic arthritis was now comparatively rare, but there had not been a corresponding reduction in the incidence of patients with valvular lesions. These patients had now, at the most, only minor manifestations of joint disease. It was too early to speak categorically of the benefits of cortisone and surgery. Time alone would provide the true perspective. Coronary heart-disease was now a disease of this age-group, and malignant hypertension continued to exact its toll; but the ætiology remained obscure and treatment was unsatisfactory. The tuberculosis death-rate in early adult life was still tragically high, but was now getting more attention in both medicine and surgery. Collapse therapy, employed so long with and without discrimination, had been largely replaced by chemotherapy and a variety of new surgical operations; but the enthusiasm for new surgical procedures was following an all-too-familiar pattern and for the moment the pendulum had swung too far in this direction. Bright's disease continued to take a substantial toll of life, and methods of treatment had gained little of real value from a vast amount of research. Ten years ago there was a most virulent type, in epidemic form, in Ireland. Though few patients died during the acute phase, few left hospital unscathed and many were dead within five years.

A survey of the past fifty years, said Prof. Abrahamson, offered a curious contrast between the most melancholy period in the history of mankind and the most illustrious era of medical progress. No doubt in the next half-century many of the diseases discussed in this symposium would have been prevented.

Scientific Sections

PATHOLOGY AND BACTERIOLOGY

President: Prof. M. H. O'Connor

Recent Advances in Active Immunisation

Dr. H. J. **Parish** (London), opening this discussion, quoted figures to show the success of the campaign for immunisation against diphtheria; in 1901 the disease had caused 10,000 deaths, but by 1951 this terrible total had fallen to 32. The question of what was the best antigen to use remained undecided. Formolised toxin was the basis of all prophylactics, and the alum-precipitated toxoid (A.P.T.), selected in 1940 for the Ministry of Health's immunisation scheme, had been the most widely used. Some recent work suggested that it might give a greater degree of protection if three injections were given at 3, 6, and 18 months of age. The new prophylactic, purified toxoid aluminium phosphate (P.T.A.P.), was a purified antigen with the advantage of containing much less bacillary protein than A.P.T. Whooping-cough had caused over 9000 deaths in England and Wales in the past ten years, and though a successful method of vaccination was available there was no reliable test of antigenicity. In a M.R.C. trial over 7000 children between the ages of 6 and 18 months were divided into two groups. Half of them received three doses of pertussis vaccine at monthly intervals, and the others were given an anticatarrhal vaccine. The attack-rate per 1000 child-months was 1·45 in the pertussis-vaccinated and 6·72 in the control group. Those in the first group who did develop whooping-cough had a mild and short form of the disease. Five kinds of vaccine are available, and the two prepared by Dr. Kendrick in Michigan seem to be the best. Early vaccination was desirable—at 2–3 months or even earlier. Three doses were given at monthly intervals, and a yearly boosting dose was probably justified. Some very recent work had suggested that a living vaccine was best in mouse-protection tests, and human trials were being carried out. On the whole, reactions after pertussis vaccination were more severe than after diphtheria immunisation, but Dr. Parish thought that too much emphasis had been placed on the risk of encephalopathies. The hope of the future lay in combined prophylaxis, which meant less injections and an enhanced antigenic response. The diphtheria-pertussis combination might carry an exceptional risk of poliomyelitis, and Dr. Parish considered that during epidemics all preventive inoculation should be discontinued. Turning to tuberculosis, he said that the effect of B.C.G. inoculation in man remained uncertain, but that it was certainly a valuable adjunct to fundamental control measures. The work reported by Palmer[1] had suggested that it was much easier to make a good vaccine than had been realised, and that it was not necessary to have large numbers of living bacilli. Wells's vole-bacillus vaccine had given encouraging results. The virulence of this organism, which is very high in the vole, was already stabilised for man and cattle, a situation which was reached with B.C.G. only after years of subculture. Dr. Parish felt, however, that the vole bacillus was unlikely to oust B.C.G.

Dr. J. **Ungar** (London) described work which demonstrated how the combination of a vaccine with diphtheria toxoid could safely enhance the antigenicity of the toxoid. Various vaccines were being used, and he thought that the mouse-protection test would enable the value of each vaccine to be assessed. Combination with a plain bacterial suspension in saline produced a rapid rise in antibody formation, but a vaccine precipitated with aluminium phosphate gave a better, if slower, response.

The virus diseases were dealt with by Dr. P. N. **Meenan** (Dublin). Influenza, he said, made its own epidemiological rules, and the A-prime virus which appeared in 1947 resisted the vaccines then available. The timing of the prophylactic inoculation may be critical, and the strain of vaccine used must be antigenically related to the organism causing the epidemic if protection was to be given. To be effective, a vaccine must evoke a high antibody response. Emulsification of the vaccine with heavy or light mineral oil to act as an adjuvant had improved its protective powers, but it then had to be given intramuscularly. Dr. Meenan thought that the trend of results was disquieting; the F.M.1 vaccine now in use would probably be less effective in future epidemics, and new vaccines would have to be tried. In poliomyelitis active immunisation was coming within the range of possibility. Inoculation with a living attenuated virus produced antibodies to the Lansing strain, and the risks could probably be minimised by an umbrella of gamma-globulin.

Clinical and Laboratory Aspects of Vitamin B_{12}

Prof. A. C. P. **Campbell** (Manchester), a vice-president of the section, took the chair for this discussion. Mr. W. F. J. **Cuthbertson**, PH.D., described his experiments, carried out in collaboration with Dr. J. N. M. Chalmers, into the excretion of the vitamin. Urinary output reached a peak about four hours after an intramuscular injection of 200 µg., and very little was excreted after seven hours. When 1000 µg. was injected, half the dose was eliminated by a normal person and about 60% by patients with pernicious anæmia. When the anæmia was in remission less of the vitamin was excreted than in relapse, but the results were not statistically significant. A dose of 50–100 µg. probably gave the maximum economical retention. After oral doses of from 3000 to 9000 μg., the excretion was much less than expected. It may be that the vitamin was taken up by the intestinal mucosa, into the abdominal lymphatics, or in the liver. Lymphatic absorption seemed unlikely because the excretion following intramesenteric injections at laparotomy was much the same as that after intramuscular injection.

---

[1] Palmer, C. E. *Lancet*, 1952, i, 935.

Dr. G. I. M. Ross (London) said that a method of microbiological assay of vitamin B_{12} was now available. The green alga, *Euglena gracilis*, required about 6000 molecules of the vitamin for each of its cells, and could be used to estimate amounts down to 1 μμg. The normal serum concentration of vitamin B_{12} was about 30 μμg. per ml. A deficiency of the vitamin occurred in megaloblastic anæmias other than pernicious anæmia—e.g., those associated with pregnancy, steatorrhœa, and total gastrectomy. It was found that those patients with a normal serum level responded to folic acid but not to vitamin B_{12}. Repeated daily injections of vitamin B_{12} produced a saturation effect; the serum level became higher as excretion diminished. Folic acid had been shown to have no effect on the concentration of the vitamin in the serum.

Taking up the clinical side of the story, Dr. C. C. Ungley (Newcastle upon Tyne) said that the value of the vitamin was confined to the megaloblastic anæmias. He had found that the megaloblastic anæmias of pregnancy and the puerperium seldom responded to vitamin B_{12}, but whole liver or folic acid were usually effective. In these anæmias, dietary deficiency was unusual. In the tropical megaloblastic anæmias dietary deficiency was the rule, and therefore B_{12} was effective. He had had a patient whose anæmia followed total gastrectomy, and who had responded well to 1000 μg. of B_{12} by mouth. The fish-tapeworm anæmia of Finland had often been attributed to some toxin in the worm, but the dried worm itself was curative by mouth, suggesting that the living worm took up vitamin B_{12} in the intestine. The response in idiopathic steatorrhœa was variable; and the megaloblastic anæmia associated with thyrotoxicosis did not respond to B_{12} but did so to folic acid. Dr. Ungley thought that the anæmia which may develop after an intestinal anastomosis was the result of bacterial activity in a stagnant loop of bowel. The bacteria may spread to the rest of the small intestine where the *Bact. coli* absorb vitamin B_{12}, leaving less for the patient.

MEDICINE

President: Prof. Henry Moore

Clinical Use of Cortisone

Professor Moore described the arrangements under which supplies of cortisone became available in Ireland in the summer of 1950. The work was carried out by a team selected by the Medical Research Council of Ireland; and 70 patients with rheumatoid arthritis had been treated with cortisone. Its effect in 500 ophthalmological cases, and in several other conditions—e.g., Simmonds's disease, rheumatic fever and carditis, status asthmaticus, and anuria—had also been studied. Though he regarded the discovery of cortisone as one of the most important advances in medicine in his time, no doctor, he said, should use this potent hormone without first mastering the literature on the subject and without strict supervision in order to detect unfavourable side-effects.

Prof. D. K. O'Donovan (Dublin) surveyed the results achieved with 1100 g. used in two years by the cortisone committee of the Medical Research Council of Ireland. 52 cases of rheumatoid arthritis were treated: and he considered that this disease was the first choice for cortisone in medicine; severe or rapidly recurring asthma, and particularly status asthmaticus, not amenable to other treatment, was his second choice; and early rheumatic carditis his third. The side-effects of cortisone included psychotic changes (which developed in 5 cases), local sepsis (3), and water retention, diabetes mellitus, subarachnoid hæmorrhage, "moon-face," epilepsy, angina pectoris, and hypertension (1 each). Dying patients were, he thought, resistant to the beneficial action of the drug.

Prof. E. J. Conway, F.R.S. (Dublin), described experiments with deoxycortone acetate and cortisone at the department of biochemistry, University College, Dublin.

Adrenalectomy in rats produced pronounced changes in the level of glucose-6-phosphate and fructose-6-phosphate in muscle with some increase in adenosine triphosphate and phosphocreatine. Cortisone and deoxycortone acetate restored these levels, but cortisone did so more effectively than deoxycortone. Both substances were given in 2 mg. injections daily. Cortisone increased nitrogen excretion in young rats, and inhibited their growth, whereas deoxycortone had little or no such effect.

The action of cortisone and deoxycortone on the sodium and potassium levels of plasma and muscle depended on the amount of sodium in the diet. On a low-sodium diet, cortisone and deoxycortone both increased the sodium and decreased the potassium levels of plasma, but the effect of cortisone was somewhat greater than that of deoxycortone. With a high-sodium intake, the effect on the plasma-sodium level disappeared. The plasma-potassium level was still reduced, but here deoxycortone was more effective than cortisone. The muscle levels generally followed those of the plasma, but it was noteworthy that an appreciable decrease in plasma-potassium was associated with distinct increases in muscle sodium, even when a fall in plasma-potassium was produced by a potassium-free diet. Such changes would appear to be secondary to those in the plasma. The final control lay in the nephrons of the kidney.

In yeast large-scale active transports of sodium and potassium could be demonstrated and interpreted in terms of a "redox pump" mechanism. The effect of deoxycortone, cortisone, compound F, and eight other steroids (other than adrenal) on the active extrusion of sodium and active absorption of K ions in yeast was examined. Deoxycortone, even in *M*/40,000 strength, had a definite inhibitory action on the active sodium and potassium transport. Cortisone had some effect, but not so great, and compound F gave a small but definite stimulus to the active potassium transport. No effect was produced by the various other steroids. This fundamental action of the adrenal hormones on a primitive cell such as yeast could be used to interpret the mechanism of action in the animal organism.

Professor Conway hoped that this and subsequent work would clarify the mode of action of cortisone in the human body.

Dr. Bernard Schlesinger (London) gave an account of his experiences with A.C.T.H. and cortisone in rheumatic fever. He thought it was too early to draw any definite conclusions as to their value. Pyrexia and arthritis disappeared within a day or two, but chorea was uninfluenced. Only a long follow-up would elucidate finally whether serious permanent valvular lesions could be prevented.

Dr. C. J. McSweeney (Dublin) described cases of early rheumatic carditis in which cortisone had been given. Pyrexia and arthritis had quickly subsided and the heart had remained normal; but in one late case, with an old-standing mitral lesion, the subsidence of acute symptoms during a recrudescence had not been accompanied by improvement in the heart clinically or electrographically.

Prof. R. H. Micks (Dublin) referred to a series of cases treated by Dr. J. A. Wallace and himself. He thought that cortisone hastened the recovery of patients with acute rheumatic carditis. Chronic rheumatic patients did not appear to respond to cortisone.

Dr. W. S. C. COPEMAN (London) described his results with 20 selected cases of rheumatoid arthritis treated over a period of two years. In only 1 of these was it possible to omit cortisone after five months' continuous treatment. This patient had now remained well for a year without cortisone. Of the 20 patients 17 had been able to return to work, but they were still on treatment. Dr. Copeman stressed the value, in deciding dosage, of clinical assessment by methods he had already published—e.g., occurrence of spontaneous pain, measurement of joint tenderness, and muscular strength as shown by grip—rather than by the estimation of erythrocyte-sedimentation rates and urinary ketosteroids or corticoids. He placed the optimum dosage for these cases at 75 mg. a day or less. Major side-effects were not seen in any of his patients.

Dr. JOHN MOWBRAY (Dublin) gave an account of 5 children with rheumatoid arthritis, and emphasised the value of low dosage. The criterion should be the lowest dose which would allow painless movement of the affected joints. The average dosage was 50 mg. daily for a few weeks, followed by a maintenance dose of 25 mg.

Dr. F. J. LAVERY (Dublin) discussed local use of cortisone in 650 ophthalmological cases, and its systemic use in 10 others. In those conditions which benefited from cortisone, local application had been found satisfactory when the anterior segment of the eye alone was involved. The conditions which responded best to cortisone in his experience were phlyctenular ophthalmia, interstitial keratitis, iridocyclitis, and sympathetic ophthalmia. Cortisone should be used with caution in virus infections of the eye.

Sir JOHN MCNEE (Glasgow), summing up, said he regarded cortisone as an empirical remedy, because there was no exact knowledge as to how it worked. He thought its use in rheumatoid arthritis and in certain eye conditions was indicated; but he deprecated, as did many other speakers, its indiscriminate use without proper control in hospital.

CHILD HEALTH

President: Prof. ALAN MONCRIEFF

Subdural Hæmatoma

Dr. C. M. SAUNDERS (Dublin) described the various types of cerebral hæmorrhage encountered in the newborn baby. Cerebral hæmorrhage, he said, is one of the main causes of neonatal mortality and affects premature babies more often than mature babies, in a ratio of about 20 to 1. In premature babies some 60% of the hæmorrhages occurred after a short second stage, whereas in mature babies they occurred when labour was long or difficult. In these circumstances, sedation of the mother, anæsthesia, episiotomy, and a low forceps delivery might prevent hæmorrhage.

Dr. A. P. BARRY (Dublin) pointed out that natal causes such as trauma, anoxia, or precipitate labour account for about 60% of cases of cerebral hæmorrhage, but in the remaining 40% obstetric factors were not responsible. Prenatal factors, such as fœtal anoxia due to maternal anæmia, toxæmia, direct uterine trauma, or genetic causes, might predispose to hæmorrhage, and postnatal factors such as anoxia and infections might also play a part. By ensuring that during pregnancy the mother received a suitable diet, with iron and vitamins, the frequency of prematurity might be diminished and the susceptibility to hæmorrhage might be lessened.

Dr. W. R. F. COLLIS (Dublin) described some of the clinical features of subdural hæmatoma seen in 5 babies (4 of them breech deliveries) at the Rotunda Hospital during the past eighteen months. Separation of the cranial sutures was often striking, and it might develop within a few days. Facial asymmetry resulting from rapid increase in skull circumference might persist after the subdural hæmatoma had been treated. The clinical suspicion of subdural hæmatoma could be confirmed by subdural tap, and in some cases up to 10 ml. of blood was found. The residual encapsulated hæmatoma may require surgical removal, and Mr. J. P. LANIGAN (Dublin) described the routine surgical procedure in these cases. A subdural effusion of clear fluid with a high protein content might arise after the blood from a subdural hæmatoma had been absorbed, and unless this was removed surgically damage to the underlying brain would follow.

Dr. AGNES MACGREGOR (Edinburgh), who described the pathological features, based her remarks on 101 cases of subdural hæmatoma seen post mortem at the Royal Hospital for Sick Children, Edinburgh, over a period of four years, during which 1000 necropsies on stillbirths and infants were performed. A quarter of the hæmorrhages were in stillbirths and most of the remainder in babies dying within two days of birth. In these fatal cases a tentorial tear was usually present and blood had accumulated below the tentorium. In the infants surviving for a time, the hæmorrhage usually accumulated over the vertex and arose from a tear of the small veins which drain from the surface of the brain into the superior sagittal sinus. Organisation of the blood-clot took place almost entirely from the dural surface and the arachnoid played little or no part. This process was often rapid and vascular granulation tissue might develop within ten days. The complications encountered included damage to the underlying brain by pressure, hydrocephalus, and ossification. This latter condition might cause irritation of the cerebral cortex.

Dr. J. P. M. TIZARD (London) discussed the prognosis in a series of 169 patients treated by the accepted methods. The immediate mortality was 3%, and in over two-thirds of the survivors the mentality appeared to be normal. In some of these, more detailed assessment by intelligence tests and other means showed that mental development was somewhat retarded. Hemiplegia and convulsions also developed in some of the cases.

Treatment of Primary Tuberculosis

Dr. F. J. W. MILLER (Newcastle upon Tyne) described a series of 2567 children suffering from primary tuberculosis who had been followed up for at least two years. 41 of them had developed miliary tuberculosis or tuberculous meningitis. In view of the infrequent occurrence of complications he considered that streptomycin and *p*-aminosalicylic acid (P.A.S.) should not be given to children with uncomplicated primary tuberculosis. There were, however, special indications for giving these drugs. They were of value (1) in children in whom the primary complex was associated with an acute febrile illness but in whom radiography did not reveal miliary spread; (2) in children with aspiration bronchopneumonia from a primary complex; (3) when a lymph-gland had penetrated the bronchial wall and had been expectorated; (4) in primary tuberculosis of the tonsil with large cervical glands; and (5) in those cases of primary skin tuberculosis which failed to heal.

Dr. M. HALL (London) outlined the routine treatment for children with primary tuberculosis. They were best treated at home, but if there was danger of further infection at home they should be admitted to a hospital where education could be provided. The children were on bed rest, adequate diet, and vitamin D and calcium gluconate. Streptomycin and P.A.S. were given to children under one year of age or if there was ulceration of the bronchial mucosa. The diagnosis of endobronchial disease was made by bronchoscopy—a procedure also indicated for collapse of a lobe, to relieve symptoms of compression such as stridor, and as a preliminary to surgery in the few cases in which this was necessary. A persistent infection of the upper respiratory tract was present in a number of cases and could be relieved by giving streptomycin nose drops, but sometimes removal of tonsils and adenoids was necessary.

Mr. Denis Browne (London) said that the tonsil infected with tuberculosis was pale, small, and often thought to be harmless. In 50 children with active pulmonary tuberculosis the tonsils and adenoids were removed, and in about a third of them virulent tubercle bacilli were isolated. In 50 control cases with a positive tuberculin reaction, but in whom the disease was inactive, no tubercle bacilli were found in the tonsils and adenoids.

Dr. R. McL. Todd (Liverpool) described a controlled trial designed to assess the value of P.A.S. in primary tuberculosis. Alternate cases of primary pulmonary tuberculosis in four age-groups, admitted to Alder Hey Children's Hospital during 1951, were given P.A.S., while the remainder did not receive any specific therapy. All cases were at rest in bed for three months and were given a diet adequate in protein, calories, and vitamins. The progress of the "trial" and "control" groups was judged by the clinical response (appetite, vitality, temperature, pulse-rate), serial white-cell counts, serial sedimentation-rates, weight gain, and serial chest radiographs, and by development of complications, and was found to be similar in both groups. Complications, such as miliary tuberculosis, tuberculous meningitis, and spread of the tuberculous process locally in the lungs, occurred in both groups but only in children under the age of three. It was felt that the use of streptomycin and P.A.S. was justified in children under three years of age suffering from primary tuberculosis. Preliminary results with isonicotinyl hydrazine were encouraging.

Dr. B. M. Dunlevy (Dublin) described the work of the public-health department in Dublin during the past five years. During this period there had been a fall in the mortality-rate from tuberculosis of 44% in adults and 74% in children. This achievement had resulted from the adoption of a number of measures. B.C.G. vaccination was introduced in 1948 for babies born to tuberculous mothers, and it was later offered for all newborn babies. At the present time 35–40% of all babies born in the maternity hospitals were vaccinated with B.C.G. No case of miliary tuberculosis or tuberculous meningitis had occurred in the vaccinated children despite continued contact with cases of active adult phthisis. Mass radiography of expectant mothers was also undertaken, and when several cases of primary tuberculosis were notified in children from a particular school, all pupils in that school were submitted to radiography. The number of beds for adults in sanatoria had been increased so that shortly there should be no waiting-list for admission. This would considerably reduce the risk to children in their homes.

CARDIOLOGY

President: Prof. Leonard Abrahamson

Rheumatic Heart-disease

Dr. William Evans (London), *opening the discussion*, concerned himself chiefly with diagnosis. One of the main errors, he thought, was caused by the combination of an innocent systolic murmur and a history of rheumatic fever. Just as a large proportion of patients with rheumatic heart-disease gave no history of acute rheumatism, so also many had acute rheumatism with no permanent cardiac lesion. It might therefore be a good idea for students to form their opinion about a murmur before they inquired about the history. Another source of error was the physiological third heart-sound which was often misinterpreted in various ways, though if heard as a clear sound in a child it was to be regarded as a sign against mitral disease. A trivial systolic murmur was nearly always innocent, and it was a good thing for the cardiologist to be a little deaf so far as this type of murmur was concerned. Whether loud or soft, this murmur should not lead to the use of the term mitral incompetence, the existence of which could only be certain when there was mitral stenosis. As rheumatic carditis must be regarded as the most important form of heart-disease from the social point of view, Dr. Evans felt that a long-term plan for its prevention was urgently necessary; this would include compulsory certification and special hospitals with teams of research-workers.

Valvulotomy for mitral stenosis figured prominently in the discussion; *and* Dr. Charles Baker (London) dealt particularly with this. Among contra-indications to the operation, he mentioned active rheumatism (of which he did not think the erythrocyte-sedimentation rate was a reliable index), and the lack of sufficiently severe symptoms. In reply to a question, he said that the youngest age at which the operation could be contemplated was automatically determined by the presence of the valve lesion and its pulmonary effects.

Sir John Parkinson (London) pointed out that the operation was palliative rather than curative, and that many patients with rheumatic heart-disease lived long and active lives. Both he and Dr. Evans acknowledged the great contribution of the Guy's workers on mitral valvulotomy.

Dr. Gerald Thomas (Taplow) spoke on the clinical diagnosis of latent active carditis, and the need for careful heart examination in a child with vague limb pains and poor general health. It was occasionally difficult to differentiate rheumatic valve lesions from congenital defects, particularly atrial septal defects. In acute carditis, the diastolic murmur, which could appear in a matter of days, was of course very important; but the systolic murmur was hard to assess, though if it increased or appeared first when pyrexia and tachycardia were regressing it was more significant. Pericardial friction and subcutaneous nodules were strong evidence of activity. At Taplow the corrected Q–T interval and the heparin resistance were no longer thought to be reliable guides. Remarkable recovery could often follow acute rheumatic carditis; and Dr. Thomas described instances in which considerable cardiac enlargement and diastolic murmurs had disappeared within a few weeks.

Dr. Walter Somerville (London), discussing the treatment of chronic rheumatic carditis, thought that there was little new or dramatic to be said. He noted, as all cardiologists have done, a general reluctance to use digitalis in heart-failure with normal rhythm and, more rarely, its excessive use with the production of toxic effects. Such effects included abnormal rhythms, and if these prompted a further increase in dosage things went from bad to worse. Severe salt restriction could be harmful, especially if combined with mercurial diuretics. The method of restricting sodium absorption by means of resins could also have unfavourable effects, and until more was known about these resins they were perhaps best left in the hands of those investigating them.

Dr. Paul Fourman (Oxford) described the mechanisms by which low-salt diets and mercurial diuresis produced adverse symptoms; and Mr. T. C. J. O'Connell (Dublin) spoke of his experience in mitral valvulotomy. He thought that, so far from increasing mitral regurgitation, the operation often lessened it.

Summing up, Professor Abrahamson thought it remarkable that infective endocarditis had not once been mentioned in the discussion. Perhaps this reflected a tendency to regard this problem as more completely solved than it really was.

CONGRESS OF THE INTERNATIONAL DIABETES FEDERATION

The first International Congress of the International Diabetes Federation was held on July 7–12 in the delightful setting of the old university town of Leiden, with the hospitable Dutch as hosts. It was attended by some 250 delegates from 19 different countries, including such honoured names as Dr. Elliott P. Joslin, Prof. Charles H. Best, Dr. R. D. Lawrence, and Dr. H. C. Hagedorn. This congress was a success despite the many language and other difficulties which beset such international meetings.

HYPERGLYCÆMIC FACTOR OF THE PANCREAS

In the Banting lecture, sponsored by the British Diabetic Association, Prof. Christian de Duve recalled that Bürger had originally described the hyperglycæmic factor of the pancreas under the name of glucagon; and he suggested that this word should be generally adopted. Bürger had described its glycogenolytic action on dog's liver, but this knowledge was only later associated with the transient hyperglycæmia observed after the administration of relatively crude insulin preparations. Fresh interest was aroused in the subject when Abel's method of crystallising insulin was superseded by that of Scott and Fisher, which, nevertheless, allowed noticeable amounts of the glycogenolytic factor to contaminate the insulin crystals. Glucagon assays were performed on rabbits which received 30 units of insulin intravenously and in whom the amount of glucose required to maintain the blood-sugar was then measured. Glucagon preparations freed of insulin acted as strongly when administered subcutaneously as intravenously, although on subcutaneous administration the effect of glucagon was masked in the presence of insulin. Sutherland and Cori demonstrated the glycogenolytic effect of glucagon on liver slices in vitro, even in association with insulin.

Glucagon was presumably a protein since it was destroyed by proteases. In many ways the glycogenolysis initiated by glucagon simulated that due to adrenaline, both apparently acting on the same hepatic enzymes. Like adrenaline, glucagon depressed the level of circulating eosinophils, although this action might be mediated through the hyperglycæmia. That glucagon was distinct from adrenaline was shown by its lack of action on the heart, blood-pressure, and muscle-glycogen. Fœtal pancreas was relatively rich in glucagon and also in islet tissue, and the same was true of dog pancreas after ligature of the duct. These facts suggested that glucagon was probably present in the pancreatic islets; but from the observation of a nearly normal glucagon content in the pancreas of alloxan-diabetic rabbits in which no insulin could be demonstrated, it seemed likely that the α cells were the source of glucagon. Van Campenhout and Cornelis had found that cobalt chloride caused extensive selective but transient injury to the pancreatic α cells of guineapigs, and the glucagon content of the pancreas was reduced by about 60%.

With regard to the clinical importance of glucagon, it might be possible to define two types of pancreatic diabetes: (1) with deficiency of both the α and β cells, and (2) with deficiency of the β cells only. It was well known that totally pancreatectomised (type 1) patients required less insulin than many spontaneous (? type 2) diabetics: and experimentally metahypophyseal and alloxan diabetes needed more insulin than the diabetes of completely pancreatectomised animals. These differences had been attributed to the absence of the exocrine secretions of the pancreas in the pancreatectomised animals, with consequent malabsorption of food: but the work of Candela and his team tended to discount this suggestion. Tying off the pancreatic duct of alloxan-diabetic dogs did not reduce their insulin requirement, but removal of the sclerosed pancreas did do so. This work had received further support from Cavellero and Malandra in Italy, who raised the insulin requirement of a pancreatectomised rat by grafting into it the pancreas from an alloxan-diabetic rat.

The function of glucagon in the intact animal remained an enigma. Bornstein et al. found a hyperglycæmic principle in the pancreatic venous blood of diabetic animals treated with growth hormone. This suggested that at least some of the diabetogenic activity of growth hormone might be mediated by glucagon, especially since purified growth hormone was not a powerful peripheral inhibitor of insulin. Glucagon remained indeed the most effective natural insulin antagonist, and the recent work of Tyberghein had shown that anti-insulin activity might occur without any net loss of liver-glycogen. Possible clinical applications of our knowledge of glucagon were now being recorded. McQuarrie, for instance, had described two cases of spontaneous hypoglycæmia where no α cells were demonstrable in the pancreas.

INSULIN

Dr. D. R. Drury (Los Angeles) presented isotope data which indicated that, although insulin has an immediate effect in transferring glucose into cells, this may be separated from its rôle as catalyst for the oxidation of glucose, this latter effect being inhibited by the simultaneous administration of β-hydroxy-butyrate.

Dr. J. J. Groen (Amsterdam) presented the latest information on his assay of blood insulin by the rat-diaphragm method. While there was reason to believe that this test was specific for insulin, its main drawback was the wide variation in response of different rat diaphragms and the extremely small differences of glucose content which had to be measured in the fluid bathing each quarter rat diaphragm.

Dr. K. Hallas-Møller and Dr. M. Jersild (Copenhagen) presented laboratory and clinical data bearing on the new crystalline and amorphous insulin-zinc compounds with long action. These products of the Novo Terapeutisk Laboratories are prepared with thrice-crystallised insulin and have not so far produced any sensitivity reactions in patients. They offer similar advantages to N.P.H. insulin but are more accommodating, as by the use of judicious mixtures most patients' requirements can be met by a single daily injection.

RAPID BLOOD-SUGAR TESTS

Any gap in the proceedings was ably filled by Dr. H. L. C. Wilkerson, of the U.S. Public Health Service. He demonstrated his machine for performing screening blood-sugar tests at the rate of 120 an hour, and described the results of his extensive surveys for new diabetics in the U.S.A.

ALLOXAN DIABETES

The session on alloxan diabetes opened with a stimulating review by Prof. M. G. Goldner (New York). Dr. J. L. Rodriguez-Miñon (Madrid) suggested that in chronic alloxan diabetes in dogs progressive damage to the pancreatic β-cells might be due to hyperglycæmia, for there was a latent interval of up to 3 months from the last dose of alloxan before diabetes became apparent. Dr. F. D. W. Lukens (Philadelphia), however, doubted whether the hyperglycæmia had been sufficient to cause this delayed onset of diabetes. Dr. A. Lazarow (Cleveland) described the spontaneous disappearance of hyperglycæmia and glycosuria in alloxan diabetic rats after 12–18 months of the disease, but much work remains to be done on the mechanism of this recovery.

CHOLESTEROL METABOLISM

The congress shared two sessions in Amsterdam with members of the 1st International Dietetic Congress.

At one of these Prof. Ancel Keys (Minneapolis) suggested that the incidence and severity of atherosclerosis could be correlated as well with total serum-cholesterol values as with any of the other more detailed results of fat studies. Furthermore the serum-cholesterol level depended more on total fat intake or the proportion of dietary calories derived from fat, than on the actual cholesterol content of the diet.

Dr. Groen then described his group's well-controlled studies on 60 normal volunteers who ate in turn each of three diets. The first had a high fat and animal-protein content, while the second consisted mainly of vegetables and contained only 1·5 mg. cholesterol per day; the third was a normal frugal Dutch diet. The results showed a significant difference in serum-cholesterol values between the dietary periods, but a great individual variation was also apparent. Any form of stress also seemed important in lowering the serum-cholesterol with a subsequent, often pronounced, rise in the convalescent period. Dr. Groen concluded that these findings helped to bridge the gap between those who maintain that atherosclerosis is mainly of metabolic origin and those who point to its common occurrence in individuals who live a stressful life.

BLOOD LIPIDS

Back in Leiden, Dr. J. Möllerström (Stockholm) described his group's work on the blood lipids in diabetes. The postprandial chylomicron count rose significantly more steeply in ketotic diabetics than in balanced diabetics; and in diabetics as a group there was some correlation of increased lipæmia with diabetic complications, particularly neuropathies. Studies on urinary choline established a direct relationship between its level and that of blood phospholipids.

DIABETES AND SEX

Dr. T. Brakier-Zelkowicz (Louvain) suggested that the increased incidence of diabetes in middle-aged women might possibly be due to their excessive caloric intake; but Dr. Joslin pointed out the relatively smaller diabetic incidence in single women than in married women with children. It was clearly important to consider these classes separately when studying the incidence of diabetes.

Dr. Wilfrid Oakley read a most useful paper on the prognosis in diabetic pregnancy, based on an analysis of over 700 cases, nearly 300 of which he had observed personally. Maternal mortality, he said, had been reduced to 1·4% at King's College Hospital, London, but the fœtal mortality remained at 20-25% even when the maternal diabetes was well controlled. This high residual mortality could not be ascribed to duration of the diabetes, its severity, or the presence of moderate complications at the time of conception. Even the toxæmic mothers had only a slightly greater fœtal mortality than that of the whole series. The cause of the high fœtal mortality remained unknown. Dr. Oakley described the reasons for performing cæsarean section at the 36th week, which, although it raises the neonatal death-rate, more than compensates for this by lowering the intra-uterine death-rate.

Dr. C. van Beek (Leiden) reviewed her extensive experiences of necropsy findings in stillbirths and neonates of diabetic mothers. The moral, she thought, was that benign renal glycosuria should not be diagnosed lightly, especially where there was a history of previous stillbirths or of large babies, because in her experience this had not uncommonly included true diabetics.

DIABETES AND THYROID DISEASE

Dr. Frank Allan (New York) reviewed the experience of the Lahey Clinic on coexistent diabetes and thyroid disease, and emphasised how the presence of one of these could mask the other.

RÔLE OF KIDNEY

Interesting experimental work on the part played by the kidney in the production of alloxan diabetes was reported from Professor Jimenez-Diaz's institute in Madrid: but at the close of the discussion there were at least two factions; one believing the kidney to be potentially diabetogenic, and another ascribing the results to possible adrenaline activity.

DIABETIC NEUROPATHY

Dr. M. M. Martin (London) suggested that autonomic nerve damage constituted the earliest phase of diabetic peripheral neuropathy, and this would explain its diverse manifestations.

ELECTROLYTE STUDIES

Dr. John Stowers (London) gave an account of electrolyte studies performed during glucose and glucose-insulin tests. The decrease in serum and urinary phosphorus was interpreted as evidence of utilisation and storage of glucose in the periphery, and corresponding changes in potassium were thought to parallel glycogen formation in the liver.

DIABETIC KETOSIS

Dr. G. A. Wrenshall (Toronto) gave the results of his work on the acetone content of exhaled air in normal and diabetic subjects. Parallel chemical and mass-spectrometric determinations agreed well, and showed that even balanced diabetics exhaled more acetone than normals and that young diabetics exhaled more than older ones. In young, but not in older, diabetics increasing blood-sugar was associated with increasing acetone content of the breath.

Dr. J. D. Nabarro gave a commendably clear account of metabolic studies at University College Hospital, London, on patients with severe diabetic ketosis. He drew useful conclusions with regard to replacement therapy and in particular to the importance of potassium in the fluid recommended for the intracellular repair phase.

COCARBOXYLASE

Results were reported by Prof. R. Boulin's team in Paris on the value of cocarboxylase in the treatment of diabetic coma. They claimed that significantly less insulin was needed by the cases receiving cocarboxylase, in comparison with cases treated similarly but without cocarboxylase.

UTILISATION OF PENTOSES

Considerable interest was aroused by the report of Dr. M. Loos (Hamburg) on the utilisation of pentoses by diabetics. Xylose caused depression of the serum-phosphorus in diabetics without insulin, reduced glycosuria and ketosis when substituted for glucose in the diet, and caused no undesirable side-effects. He felt that pentoses deserved further investigation with regard to their utilisation in diabetics and their use in diabetic diets.

CONCLUSION

Dr. Lawrence, as the pioneer of the first national diabetic association to be formed, had a leading rôle in the congress. This was of great value in bringing together workers from many lands; but possible small improvements for the next such meeting also suggested themselves. One need is for clearer and properly labelled slides rather than illegible tables, to be projected on the screen; and a single definition should be adopted for "diabetic coma."

MEDICAL RESEARCH COUNCIL

THE latest annual report of the Medical Research Council[1] contains, in its introduction, a brief account of the ways in which the council is fostering the training of research-workers.

Far and away the best training for a research-worker is to engage in actual investigations under the eye of an acknowledged expert. This is easy to arrange when the chosen field of research has been the subject of his undergraduate studies. But a new graduate may wish to be trained for research in a sphere with which he is unfamiliar —for example, in one of the several important biological subjects that are judged unsuitable for the undergraduate curriculum—or he may wish to enter a field which spans more than one subject, or to refresh or extend his knowledge of one of the basic sciences after some years spent in purely clinical practice.

> "Problems of this kind arise to-day in connexion with practically every branch of biological or medical research. In catering for the training of research workers in medical science it is necessary therefore to provide opportunities not only for those who need a further period of training in their own subject but also for those whose training is lacking in some important particular or who wish to work in a subject suitable only for postgraduate study. With these considerations in mind the Council have recently reviewed their arrangements for training research workers and now have three special schemes for this purpose: postgraduate studentships (to be known in future as postgraduate scholarships); clinical fellowships tenable in this country; and travelling fellowships."

The council now covers a wider field than ever before; and the following passages, abstracted from the report, refer to only a little of the work completed or in progress.

PROTEINS

To acquire information about the size and shape of the molecules of purified proteins various physical methods have been used. The ultracentrifuge provided accurate knowledge about molecular weights. The electron microscope is being used at the National Institute, and the council's Biophysics Research Unit at King's College, London, to discover the molecular shape of some of the larger proteins or protein-complexes such as viruses. Many proteins have approximately spherical molecules and can often be obtained in the form of crystals, whilst others, such as the contractile protein of muscle, have long fibrous molecules. Both types of protein have been examined by X rays. Although the discovery of the exact position of each atom is a goal that will probably be attained only in the distant future, considerable progress has been made in defining the general shapes of certain protein molecules. It has been clearly shown that the amino-acids are arranged in chains of a regular geometrical form, parallel to the main axis of the molecule, and that the chains are arranged in a regular pattern relative to one another. The chains are folded to give a compact molecule; and recently it has been suggested that they are in the form of a spiral containing eighteen amino-acids to every five turns.

On the building up and breaking down of proteins our knowledge has advanced greatly, partly because of chromatography but even more because of the introduction into biological research of stable and radioactive isotopes, with which the changes undergone by different substances in the body can be traced in detail. From isotope work it is now known that the proteins of the blood-plasma, the liver, the kidney, and the intestinal tract are almost completely renewed every fifteen or twenty days, which makes the relative constancy of composition of these tissues most remarkable. However, this rapid turnover does not apply to all body proteins. Collagen remains practically unchanged once it is formed.

It is becoming evident that the metabolism of some amino-acids is closely connected with the formation or action of certain vitamins. It has been found that animals need a supply of labile methyl groups, and do not grow unless the diet includes choline or the amino-acid methionine, both of them sources of such groups. On the other hand, it has been shown that the rat can to a very limited extent synthesise methyl groups from other components of the diet. Preformed methyl groups can much more readily be dispensed with if the diet contains vitamin B_{12}. Similarly, a deficiency of vitamin B_{12} leads to a disturbance of the metabolism of tryptophan.

PRESERVATION OF LIVING CELLS

Among the lower forms of life certain cells, tissues, and organisms may survive freezing at very low temperatures, such as can be obtained with "dry ice" (—79°C) or liquid air (about —192°C). Thus, successful experiments have been carried out with certain bacteria, moulds, protozoa, minute worms, rotifers, and the like. Little work has been done on vertebrates, and the functional survival of normal cells of birds or mammals after exposure to low temperatures has rarely been recorded. From recent work, however, it may prove possible to verify the theoretical expectation that if a cell can be frozen to very low temperatures the arrest of biochemical processes will confer a virtual immortality on the cell while it is maintained at these temperatures. This work has important practical applications in that it will make it possible to store various cells and tissues for clinical use. In trials of the fertilising capacity of frozen bull spermatozoa, a pregnancy-rate of nearly 80% followed insemination with semen stored at —79°C for periods varying from two hours to eight days. Since then pregnancies have been obtained by the use of semen stored for several months. Similarly, it seems that endocrine tissues may survive protracted freezing; and methods are being developed for storing red blood-cells in this way.

STATISTICS IN MEDICAL RESEARCH

Nowhere in medicine has the application of the statistical method had a more salutary effect than in the testing of new agents for the treatment or prevention of disease. The council's Whooping Cough Immunisation Committee found it necessary for its trials of different whooping-cough vaccines to recruit nearly 10,000 children; since less than one in five were in the next two years in contact with a known case of whooping-cough, the incidence of attack was inevitably low; and it was only the large numbers used that enabled the positive value of the best vaccines to be decisively shown. Often, however, a carefully designed inquiry can give an answer with relatively few observations. The council's trial of the value of streptomycin in the treatment of tuberculosis in young adults used only 50 treated cases and 50 controls and gave a clear result. Similar numbers sufficed to demonstrate the improved effect when *p*-aminosalicylic acid (P.A.S.) was given in conjunction with streptomycin.

INFECTIOUS DISEASES

Whooping-cough

Nearly 10,000 children under two years old have been inoculated; half were given one or other of three whooping-cough vaccines, the other half a fluid superficially indistinguishable from the vaccines. All the inoculated children were visited once a month for two years. At the end of this period the proportion attacked by whooping-cough was five times as high in the unvaccinated children as in the vaccinated. Efforts are now being made to find the factors responsible for differences in potency between the vaccines.

---

[1] Report of the Medical Research Council for the Year 1950–51. H.M. Stationery Office. Pp. 214.

Work is also in progress to find a method by which the effectiveness of a particular vaccine can be tested in the laboratory instead of in the field. If satisfactory methods can be evolved, protection against this disease may in the near future be made available on the same scale as protection against diphtheria.

Infantile Gastro-enteritis

Further work has strengthened the conclusion that the "alpha" type of coliform organism is associated with this disease. In some outbreaks another type, "beta," has been found; and there is reason to believe that the few in which neither has been found may have been caused by another type not yet recognised. The alpha type at least is very susceptible in the laboratory to chloramphenicol, aureomycin, and terramycin, though not to penicillin.

Tuberculosis

The trials of B.C.G. and vole-bacillus vaccines are making progress; over 40,000 children of school-leaving age have entered the scheme, and the follow-up has started and will be carried on until the end of 1955. A national survey of tuberculin-sensitivity at various ages has been completed, 95,000 children and young people having been examined in twenty-two representative areas of England and Wales.

Certain non-ionic surface-active agents have been found to produce a striking antituberculous effect in the mouse and guineapig. Unlike previously known antituberculous agents, these substances have no action against the bacillus in the test-tube but seem to act on the body itself, by stimulating or accelerating the ordinary defence mechanism. The present compounds are too toxic to be used in treatment, but new methods are being developed in the hope of preparing more active and less toxic products.

A Tuberculosis Chemotherapy Trials Committee has been formed, and at its first meeting in March recommended that extensive controlled clinical trials be conducted under the auspices of the council to compare the effects of isonicotinic acid hydrazide with those of streptomycin and P.A.S. It was essential for the trials to be organised rapidly and in such a way as to provide an answer as soon as possible. By the end of April thirty-five hospitals were already coöperating, and over 200 patients had been accepted. Analyses of the results will be made as the trial progresses, so that any striking effect may be reported without delay.

ANTIBIOTICS

The Antibiotics Clinical Trials Committee has made a study of pneumonia in which all cases, regardless of their causal nature (which was, however, subsequently ascertained), were allocated to one of three groups, which were treated with chloramphenicol, aureomycin, or "standard" treatment—that is, penicillin with or without sulphonamides. Terramycin was not available when this study was begun but was included at a later date.

> "Standard treatment is so effective in the majority of cases of pneumonia that a significant difference in mortality was not to be expected in any but a very large series; there were, however, slightly fewer deaths in patients treated with penicillin, and by other criteria there was little to choose between the three groups except that penicillin produced fewer undesirable side effects than either chloramphenicol or aureomycin."

DISEASES OF THE EYE

Much of the Ophthalmological Research Unit's time during the past year has been spent in studying the effects of cortisone. Largely because of its ready absorption on local application, diseases of the anterior segment of the eye are pre-eminently suitable for treatment with cortisone. Diseases of the posterior segment, for which cortisone must be given by injection or mouth, are in general much less responsive. It has been shown that cortisone is effective in controlling the acute phases of ocular inflammatory disease whether bacterial, allergic, or traumatic in origin. So dramatic is its action that in many such cases, where the life history of the disease is short or an infecting organism can be attacked by other means such as antibiotics, the results of treatment are excellent. Typical conditions wherein this occurs are acute iridocyclitis, sympathetic ophthalmitis, and infective keratitis. The effect, however, on chronic infective diseases and on the later consequences of inflammatory conditions is difficult to assess and is much less distinct. Cortisone is similarly ineffective in degenerative conditions affecting the eye. Its value in ophthalmic conditions is thus limited, but within its restrictions is great, particularly when it is remembered that the functional effects of acute or even subacute inflammatory changes may be disastrous.

SKIN DISEASE

The arms of volunteers were soaked in acetone to extract the sebum, which was found to be present in amounts equivalent to a surface film about $^1/_{1000}$ mm. thick. Some 40% consisted of free long-chain fatty acids, about half of which contained unsaturated carbon atoms and so were potentially active chemicals. Oleic acid was proved by X-ray crystallography to be a major constituent, and its disinfectant action, and that of sebum itself, on streptococci and other pathogenic micro-organisms was confirmed. Some bacteria are apparently but little affected by sebum, but these are mostly destroyed by drying; so very few harmful organisms can multiply or even survive for long on the healthy, intact skin surface. Even the staphylococcus, which is one of the most resistant organisms, has been shown to survive for only about three days. If the skin is injured, however, and serum exudes, not only does the moisture enable certain organisms to multiply but the disinfectant action of sebum is neutralised.

Skin grafts, it has now been found, can be stored in the refrigerator and used successfully several weeks later if any injured areas remain unhealed. Even more remarkable is the capacity of such isolated skin to withstand being frozen solid by liquid air, provided this is done gradually.

CORTISONE AND A.C.T.H.

The council's clinical and experimental work on cortisone and A.C.T.H. began towards the end of 1949, but its scope was at first severely limited by the extreme scarcity of the two hormones. The manufacture of both hormones continues to be difficult and this country is still almost entirely dependent on supplies from the United States. Cortisone is not manufactured here at all; but several commercial firms have become interested in the manufacture of A.C.T.H., and the first home-produced samples have already been delivered under contract to the Ministry of Health and approved on the basis of provisional specifications laid down by a specially appointed committee of the council. One obstacle to expanding production has been the scarcity of the animal pituitary glands from which A.C.T.H. has to be extracted, but it is hoped that this difficulty may gradually be overcome as a result of recent steps by the National Research Development Corporation to encourage their collection and arrange for their distribution. Another serious obstacle is the difficulty of standardising the potency and purity of the finished product, the method in use at present requiring laborious and uncertain tests on a large number of rats. Continuous, but so far unsuccessful, work in search of less complicated and more reliable methods has been in progress at several different centres.

The raw material for the commercial synthesis of cortisone has so far been deoxycholic acid, obtained from animal (mainly ox) bile, which must always remain inconveniently scarce. Every effort is therefore being made to find some more plentiful alternative of vegetable origin, amongst those first considered being sarmentogenin, which can be extracted from the seeds of a particular strain of *Strophanthus sarmentosus*, a climbing plant growing in certain areas of Africa. The possibilities were recently investigated on the spot by a team sent out by the council to Nigeria and the Cameroons; but supplies of the seed proved so inaccessible, and the best yield of sarmentogenin so small, that no immediate contribution can be expected from this source. One of the most promising naturally occurring compounds from the point of view of cortisone synthesis is a sapogenin called hecogenin, which was already known to occur in small quantities in agave species in the Southern United States and Central America. It has now been discovered by a team of council workers that hecogenin occurs also in sisal waste and in still higher concentration in the juice of the sisal plant. Investigation of this matter by a member of the team in Kenya has shown that hecogenin can be easily and cheaply extracted from the sisal juice, so that this source material for cortisone synthesis becomes potentially available in a large amount and at low cost.

SALARIES OF CIVIL SERVICE DOCTORS

Discussions arising out of the report of the Howitt Committee[1] have been continued by the Civil Service Medical Officers Joint Committee, formed by the Institution of Professional Civil Servants, the Ministry of Health Medical Staff Association, and the British Medical Association. On June 27 the Government's decision was given in the following letter from the Financial Secretary to the Treasury:

> "In the course of the discussion with the deputation from your Committee who came to see me on 13th June I promised to consider what undertaking we should give you about a future review of the salaries recommended by the Howitt Committee for Civil Service Medical Officers.
>
> "As I explained to the deputation, we do need to go ahead as soon as possible with the recruitment of Medical Officers in the Civil Service and for the reasons that I have already explained we think that the rates recommended by the Howitt Committee should first be given a fair trial. In this we should naturally hope to receive the usual facilities to advertise in the medical journals.
>
> "On this understanding I should be willing to agree that there should be a further review of the salaries of Civil Service Medical Officers not later than December, 1953, and that this review should take account not only of the results of the competitions held in the meantime but also should have regard to the general principles enunciated by the Tomlin Commission and any other relevant factors.
>
> J. A. Boyd-Carpenter."

At an emergency meeting of the Joint Committee held on July 1, it was agreed that no useful purpose would be served by continuing the negotiations with the Treasury or by seeking a further interview with the Financial Secretary. A letter later sent to the council of the B.M.A. on behalf of the Joint Committee recalls that the council last January regarded the Howitt Committee's proposals as unacceptable, and points out that "quite apart from the preliminary period of preparation and discussion the claim of the Joint Committee has been before the Treasury since August, 1949, and no progress has been made."

After a meeting of the B.M.A. council in Dublin on July 5, Dr. A. Macrae, secretary of the B.M.A., wrote to the Financial Secretary of the Treasury in the following terms:

> "I have been asked to say that the Council is disturbed to learn that you feel unable either to refer the matter to arbitration or to review the recommendations of the Howitt Committee in the light of the Danckwerts Award until after the results of the competitions are known and then not until a considerable time has elapsed.
>
> "The Council has therefore decided that in all the circumstances it will not be possible to accept any further advertisements for medical officer appointments in the Civil Service until such time as you feel able to discuss with us some alternative proposals which offer more acceptable opportunities for the officers concerned."

CENTRAL HEALTH SERVICES COUNCIL

The Minister of Health has made the following appointments to the Central Health Services Council and standing advisory committees for the period ending March 31, 1955:

CENTRAL HEALTH SERVICES COUNCIL

Medical Practitioners.—J. A. Brown, M.D. (Birmingham); Sir Ernest Rock Carling, F.R.C.P., F.R.C.S. (London); Sir Henry Cohen, F.R.C.P. (Liverpool); Prof. A. J. Lewis, F.R.C.P. (London); Wilfrid Sheldon, F.R.C.P. (London).

Persons with Experience in Hospital Management.—P. H Constable, M.A., F.H.A. (London); N. A. Ball, F.H.A. (Carmarthen).

Person with Experience in Local Government.—Fred Messer, M.P., J.P. (London).

Dental Practitioner.—J. Ballard (London).

Person with Experience in Mental Health Service.—C. F. Comer, R.M.N. (Manchester).

Registered Nurse.—Miss Eleanor J. Merry, S.R.N. (London).

Registered Pharmacist.—Alderman W. J. Tristram, M.P.S., J.P. (Cheshire).

The Central Health Services Council has re-elected Mr. Messer as their chairman and Sir Henry Cohen as their vice-chairman for the current year.

STANDING ADVISORY COMMITTEES

Medical

J. A. Brown; Sir Ernest Rock Carling; Sir Henry Cohen; Prof. A. J. Lewis; H. Kenneth Cowan, M.D. (Chelmsford); H. M. C. Macaulay, M.D. (London); S. Wand, M.B. (Birmingham); one vacancy.

Dental

F. J. Ballard; Thomas Hindle (Blackburn); Prof. Martin Rushton, M.D., F.D.S. R.C.S. (London); Clement Spiridion, L.D.S. R.C.S. (Cardiff); Prof. F. C. Wilkinson, M.D., F.D.S. R.C.S. (London).

Pharmaceutical

Alderman Tristram; P. J. Gibbons, M.B. (Liverpool); J. B. Hough, M.P.S. (Newport, Mon.); Harry Noble. B.PHARM., PH.C. (London); D. E. Sparsholt, M.P.S. (Nottingham).

Ophthalmic

Macdonald Critchley, F.R.C.P. (London); G. H. Giles, F.B.O.A. (London); O. Gayer Morgan, F.R.C.S. (London); A. E. Turville, F.B.O.A. (Northampton).

Nursing

P. H. Constable; Miss Merry; Miss Muriel Edwards, S.R.N. (London); Miss Frances Goodall, S.R.N. (London); Miss Margaret J. Smyth, S.R.N. (London); Miss May E. A. Squibbs, S.R.N. (Leeds); Miss Bertha F. H. Townsend, S.R.N. (Enfield, Middx.).

Maternity and Midwifery

Miss Merry; Miss Joyce M. Akester, S.C.M. (Chichester); Miss Lois Beaulah, S.C.M. (Surrey); Miss Zita M. Goodall, S.C.M. (Surrey); one vacancy.

Mental Health

C. F. Comer; Prof. A. J. Lewis; N. H. M. Burke, M.R.C.S., J.P. (St. Albans); K. K. Drury, M.B. (Leicester); Denis Williams, F.R.C.P. (London); Prof. O. L. Zangwill (Oxford).

Tuberculosis

Sir Brunel Cohen (London); P. M. D'Arcy Hart, F.R.C.P. (London); Peter Kerley, F.R.C.P. (London); Miss Doris Lambert, S.R.N. (London).

Cancer and Radiotherapy

Sir Ernest Rock Carling; Sir Henry Cohen; Prof. E. C. Dodds, F.R.C.P., F.R.S. (London); Sir Ernest Finch, F.R.C.S. (Sheffield); K. I. Julian (London); Prof. J. S. Mitchell, M.B. (Cambridge); V. E. Negus, F.R.C.S. (London).

In England Now

A Running Commentary by Peripatetic Correspondents

AT every meeting of the pædiatricians someone is bound to get up and say how enjoyable such meetings are because we still have so much of the child in us. Looking round the faces at our last local gathering I found this rather hard to believe and I fell to wondering what appropriate remarks are made when other specialists forgather. Do obstetricians congratulate themselves on their pregnant discussions or their speakers for their excellent delivery? Do dermatologists agree that they always get beneath the skin of their subjects and ophthalmologists that they always see eye to eye? Chest physicians, I suppose, pat each other on the back and maintain that they breathe more freely in each other's company. And cardiologists probably have heart-to-heart talks and listen to the lecturer without a murmur.

* * *

As a peripatetic electrocardiographer I have gradually learnt my way through the maze of electrical London, and I have marked on my map the islands of 110-volt, the treacherous swamps of D.C. and the deserts of gas and oil lamps. My bag resembles a museum of varied and curious fittings so that I can only be defeated by the occasional individualist who either makes his own plugs and sockets or imports them from the Continent—"I'll bet you've never seen one like this before."

Last week I had to mark a new danger area. Strangled noises from the instrument and a fantasticated base-line revealed that not only was it obliging with a rendering of "Woman's Hour," but was also trying, bless it, to write it down. "An ectopic beat?"—"No, entry of the brass, I think." On my second visit to the neighbourhood of the broadcasting station there was an additional distraction from a battery of hairdriers in the "Coiffeur des Dames" below the flat. The effort to make a simultaneous one-channel recording of a recipe for marmalade, lead one, and a realistic frizz of A.C. from the driers was too much for the machine. Or perhaps it was overcome by misogyny, for it sulkily wrote a few complexes upside-down and then clicked off in an electrical huff.

* * *

The other day, with a slight drizzle and a boisterous wind blowing, I saw half a dozen oddly assorted people sitting along the front-garden party wall between two houses in a pleasant residential district. They looked as pathetic as wet birds on a telegraph-line, each with his shoulders humped against the wind and nobody saying a word to his neighbour. Along came a housewife with a battered basket of shopping and an even more battered child, and turned in at the gate. "Full up inside?" she said to the last man, at which he and his five companions looked up, nodded, then relapsed into immobility again. They were queueing to get into the doctor's waiting-room.

Waiting-rooms have become fantastic places since my youth, when patients were received as friends of the family in the doctor's drawing-room, and fuel restrictions did not prevent a blazing fire and open windows. Since then the waiting-room has come down in the world. I remember in the Midlands during the war a doctor showing me his surgery with a rueful wave of the hand. About sixty patients sat on rows of forms in a bare gaunt room looking for all the world like a village treat waiting for the magic-lantern show to begin. Then there are those terrible surgeries in London where the doctor has acquired an old shop, with the windows perhaps still boarded up and the chairs salvaged from goodness knows what murky past. A third type is nothing more than the passage, usually graced with the title of entrance-hall, of a small suburban house, with a couple of forms against the wall, where patients sit, almost knee to knee, as though in an old-fashioned diligence, and which is as draughty, stuffy, and unwarmed as a diligence.

To make the best room of a small house do double duty for patients and family sets a housekeeper a problem, and nowadays the doctor will probably be wise, by hook or by crook, to provide a separate room. The number of his patients has risen and with it the cost of cleaning and wear-and-tear, and a room furnished for its special purpose and traffic can be at once more attractive and less expensive to maintain.

An ideal waiting-room should be easily cleared for cleaning. It should have gay washable walls and floor, some of the comfortable stacking-chairs now on the market, and magazine-racks to save space and chaos. A slow-burning combustion stove would keep it warm in winter. And I'd like to put in something to amuse the children; toys might lead to jealous outbreaks, but a dado on one wall with farmyard animals or an alphabet series would be a boon to mothers. Probably only a doctor who is building his own surgery can offer his patients the waiting-room he would like, but access to a lavatory would be a godsend to many, especially those who have to bring their children.

The patient spends perhaps seven or eight times as long in the waiting-room as he does in the consulting-room. Small wonder if he starts judging his doctor's character and professional ability by the thoughtfulness and hospitality shown.

* * *

Like many Scotsmen, my friend James is a collector of general information, on the principle that somewhere at some time it may come in useful. On the boat home somebody pointed out to him Mr. X, the working owner of a fishing fleet, watching his haddock and whiting being stored in the hold. It took James about thirty seconds to make the mæstro's acquaintance, and in another ten seconds questions were being asked and answered about the kinds of fish caught, the best places and time of year to go after them, and so forth. This pursuit of knowledge for its own sake seemed to me wholly admirable. Presently the conversation turned to the merits of various types of net. "I expect," said James, "that your nets get a good deal damaged in the course of the season?" The mæstro agreed that the net repair service was a large part of the business. "And how," asked James, "do you set about repairing a rent?" Bits of string, paper, and pencils were produced. Notes were made and practical demonstrations given. "Ah, thank you," said James at last, "that will be very useful. I have two or three small holes in my strawberry netting at home. . . ." So much for the pursuit of knowledge for its own sake.

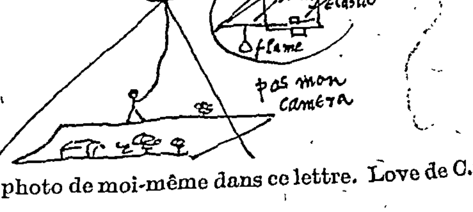
* * *

As I was passing through the outpatient waiting-hall of an East End hospital one morning about 11 o'clock, I saw a well-known figure, an elderly man, sitting on the bench. As the medical clinic did not start before 2 P.M. I suggested to him that he might go out for a meal and return later. But he replied "I insist on being seen first, as I refuse to be kept waiting."

I expect this proves something, but I don't know just what.

* * *

News from School.—"The balloon I want you to send could be in (*a*) the bread oven (most likely), (*b*) the shed, (*c*) the nursery cupboard, (*d*) the attic (not likely), (*e*) the other bread oven, (*f*) same as (*a*), (*g*) same as (*a*). I think I told you that I sent off two gas balloons. One of them came back from a place in Suffolk called Stansfield (near Sudbury) and would have gone nearly 80 miles if it went dead straight, and the second one only went about 30 miles, to Great Missenden, Bucks, where someone found it in the High Street. The two aren't on a straight line and they were sent off within about 15 min., so the first must have reached about 11,000 ft. because the winds were more westerly up there. The Sudbury one was found by a farmer while he was cutting hay. When and if you send my big balloon, I shall take an aerial photo of the School, comme ça:



J'ai mis un photo de moi-même dans ce lettre. Love de C."

Letters to the Editor

MATERNITY AND CHILD-WELFARE SERVICES

SIR,—Prof. Leslie Banks at the meeting of the British Medical Association in Dublin on July 10 made the remarkable statement that the maternity and child-welfare services, having fulfilled their main purpose, should now be merged with the hospital services, and that the "vast army of workers" engaged should be demobilised.

It will be generally accepted that these services, especially the infant-welfare services, are purely educational, and that they have never sunk to the position of mere outpatient departments for the patch-repair of bodies. It has also (up to July 10) been generally accepted that women are not born into the world with an inheritance through their chromosomes of all the knowledge necessary in this complicated civilisation to enable them to bear and rear their children in health and comfort. They have not been born, I suggest, with an understanding of the biological values of the various foods, nor of their availability.

Consequently, one would have thought that education would still be as necessary in 1952 as in 1902. But no, Professor Banks says that this education has been mainly performed, and would disband the teachers. Does this ecologist suggest that quite suddenly babies are now being born with their genetic characteristics so mutated that they now have, in addition to their normal instincts, a detailed knowledge of their nature and nurture? Does he suggest that from birth a baby can supervise the making up of his own feeds, can decide automatically the precise amount of orange-juice needed, and can guide his mother on her psychological approach, and the careful observance of those practices which can so materially affect his mental and psychological health? Can the New Baby (from July 10) ensure that his parents will not allow him to become maladjusted? Should this be Professor Banks's claim, then his name should be linked with that of the eminent Russian geneticist, Lysenko, who discovered that genetics was merely atom-fissured environment modified by an enlightened proletariat; and I would suggest that this theory might well be called, using a musical idiom, the theory of Lysenko, arranged by Leslie Banks.

There are, however, remnants, though Professor Banks does not indicate what residue the hospitals would deal with. These infants are *healthy*, and number 3,725,000. Would he admit the lot to the hospital, and if so would he send them to the wards or to the outpatient departments? It cannot be denied that either course would involve the hospital boards in some building costs, and might even interfere with the rearmament programme.

What would the medical staff do with these children? Their mothers have been "mainly educated," and so we must assume that Professor Banks does not consider they need the education they have received up to now in local-authority clinics. The hospital doctors will need guidance; will Professor Banks supply it? The hospitals (up to July 10) have only been willing to accept patients requiring treatment, but these 3¾ million kids are healthy! It is admitted that when they mix with the ill children in the germ-laden atmosphere of children's outpatient departments, a substantial number of them will be able to contract infection, and so qualify for attention; but at the most this would only involve a million or two. What about the others; and anyway, what material advantage would it be to the community, to the hospitals, or to the children to swamp the available accommodation?

Ecologists all over the world have pointed out the terrific problem confronting the world of a rapidly increasing population, and an almost stationary food-supply. The professor of human ecology at Cambridge would appear to have the answer!

Smethwick. HUGH PAUL.

SORE THROAT AND RHEUMATIC FEVER

SIR,—A report will shortly be published [1] of an inquiry into some epidemiological aspects of rheumatic fever conducted under the auspices of the Rheumatic Fever Committee of the Royal College of Physicians. May we anticipate the publication of this by commenting on a statement in your leading article last week which is in conflict with the findings of this recent inquiry?

A group of 31 rheumatic children, for whom a history of tonsillitis had been recorded before the onset of their rheumatism, was compared with a control group of 70 children who had also suffered from tonsillitis but had not subsequently developed rheumatism. It was found that 36 (51%) of the control group, but only 6 (19%) of the rheumatic group, had undergone tonsillectomy. This difference was far too great to be attributed to chance, and implied that the liability to rheumatic fever of children with tonsillitis may be reduced by about two-thirds when the tonsils are removed (i.e., 42% of the unoperated but only 14% of the operated cases of tonsillitis belonged to the rheumatic group of children). We were not, however, able with the records at our disposal to exclude the possibility that there might have been some cases in which rheumatic fever intervened between a decision to perform tonsillectomy and a suitable occasion for operating. If this were the case the advantage of tonsillectomy would have been overestimated to some extent.

The Medical Research Council Report of 1927,[2] which you cite, does not contain any direct evidence on the value of tonsillectomy: it records 60 cases in which tonsillectomy had failed to prevent rheumatic fever, but makes no comparison between operated and unoperated cases. The authors of the report concluded that "complete removal of the tonsils does not appear to afford absolute protection from attack by rheumatism," but this conclusion is compatible with the view that tonsillectomy is an effective means of reducing the incidence of rheumatic fever after tonsillitis.

DAVID HEWITT.

B.C.G. VACCINATION AND TUBERCULIN ALLERGY

SIR,—I have read with great interest Dr. Palmer's paper.[3] As one responsible for the production and supply of B.C.G. vaccine for the mass-vaccination programmes in India, Ceylon, Burma, Malaya, and Thailand, I must sound a note of warning to B.C.G. workers in mass-vaccination campaigns against interpreting Dr. Palmer's observations to imply that fresh liquid B.C.G. vaccine can be handled without any refrigeration, that the age or the dose of the vaccine does not matter, that there is a wide margin of safety, and that satisfactory tuberculin-sensitivity will follow vaccination and that there is no question of a "positive" or "negative" reactor to tuberculin as almost all vaccinated children show some degree of tuberculin allergy.

All the field investigations were carried out on Danish school-children. This seems a pity because Danish children are known to develop a very high degree of tuberculin-sensitivity after B.C.G. vaccination.

Their capacity to develop tuberculin-sensitivity is best illustrated by the observations reported by Dr. Palmer himself. "When only heat-killed vaccine was used, the average size of tuberculin reactions among them was 5 mm., about the same as that found in Egyptian children vaccinated with standard (and presumably) living vaccine in the mass campaign! More interesting still is the fact that the average reaction of children receiving standard vaccine, which had been heated to 80°C for two hours, increased from about 5 mm. at ten weeks to more than 9 mm. at one year." Were these not Danish children, the question of superinfection would have been brought in as an aid to explain this very extraordinary phenomenon.

---

[1] Hewitt, D., Stewart, A. M. *Brit. J. soc. Med.* (in the press).
[2] Social Conditions and Acute Rheumatism. *Spec. Rep. Ser. med. Res. Coun., Lond.* no. 114, 1927.
[3] Palmer, C. E. *Lancet*, 1952, i, 935.

We have therefore to assess the results of the investigations against the background, if I may say so, of a comparatively exaggerated tendency of Danish children to develop tuberculin allergy after B.C.G. vaccination; and this is bound to reflect itself in the results.

It would be interesting to speculate on the results had the field investigations been duplicated in Greece or Egypt. It is quite probable that the low tuberculin-sensitivity after B.C.G. vaccination observed in the children in Greece and Egypt would have adversely influenced the size of the tuberculin reactions in these countries, in much the same way as the high tuberculin-sensitivity of the Danish children has favourably influenced the tuberculin reactions in Denmark.

It would, therefore, seem that the observations made in Denmark are of purely local interest inasmuch as the same results cannot be reproduced in Greece or Egypt. In other words, the allergenic potency of the vaccine appears to depend not only on the vaccine but also on the capacity of the children of the particular country to develop hypersensitivity to tuberculin. Dr. Palmer has presented data from three countries to show that such variations in capacity do exist. In the circumstances, the inferences drawn from the results obtained in one country—Denmark—cannot be considered to apply to other countries.

Dr. Palmer mentions "standard preparations" from other laboratories.

So far as I know, there is no international, but only a national, standard for B.C.G. vaccine. I sent a sample of vaccine for comparative study of the potency to the W.H.O. Tuberculosis Research Office in February, 1951. I was requested to send a sample of our "usual" vaccine, and our "usual" vaccine contained at that time 0·5 mg. of semi-dry B.C.G. mass per ml., while the Danish "standard" vaccine contained 0·75 mg. per ml. Unless the Indian vaccine was excluded from the studies, the different vaccines cannot have been of the same labelled strength—not to mention the other possible variations.

It is clear that Dr. Palmer does not like the use of the terms "positive" or "negative" tuberculin reaction after B.C.G. vaccination, but prefers to measure the average size of the reactions as a convenient index of post-vaccination allergy.

Many would agree with him. But we need an expression to indicate whether B.C.G. vaccination has been successful or not. In this connection the terms "reactor" and "non-reactor" have been used by some investigators. In the case of smallpox vaccination, we speak of a successful "take." Is there no need for re-vaccination with B.C.G. even in a country like Egypt where the children are apt to develop only a low degree of tuberculin sensitivity? From the size of the tuberculin reaction how may one differentiate between a child that requires re-vaccination and one that does not?

Dr. Palmer thinks that many of our traditional concepts regarding B.C.G. vaccine may have to be discarded, as it seems they are ill-founded. Before they are discarded, it has to be convincingly shown that they are irrational or harmful. I should like to ask Dr. Palmer which of the two vaccines—one that is fresh, contains a fairly high concentration of B.C.G., and has been constantly refrigerated, or another, a month or more old, stored at 2–30°C, and containing only a small fraction of the strength of the first vaccine—he would recommend for mass vaccination in a country such as Egypt. The traditional concepts reflect great credit on the vision of the pioneers, which has made universal expansion of B.C.G. vaccination possible.

It would, in my opinion, be most undesirable for the impression to gain ground that strict refrigeration of B.C.G. vaccine is not essential or that the age or dose of vaccine does not matter, because slackness in attention to details of technique would inevitably result. I would make a strong plea that until a satisfactory dry vaccine is developed and made available for mass-vaccination programmes, there should be no relaxation of the present high standard of technique. The conditions in some remote areas in under-developed countries are already sufficiently adverse to B.C.G. vaccination; and it is undesirable to worsen them by lowering the standards.

B.C.G. Vaccine Laboratory,
King Institute, Guindy,
Madras, India.

K. S. RANGANATHAN
Director.

SURGERY OF PEPTIC ULCER

SIR,—There can be little to criticise in Sir Heneage Ogilvie's thoughtful paper on this subject (May 31). I wonder, however, whether his ingenious explanation of the lesser-curve site of ulceration is the right one? May it not be that it is the mucus, always in considerable quantity in the more dependent part of the stomach, that is responsible for its freedom from ulceration? When Lintott and I carried out our gastroscopic studies of the effect of aspirin on the stomach that conclusion seemed to us to be the obvious one.

Mr. Michael Smyth (July 5) thinks but little of the value of milk drip, and is good enough to quote a contribution of mine in support of an antacid mixture. I would like to make it clear, however, that although the effect of milk drip on gastric acidity is very variable, yet this treatment is the most certain means of abolishing pain *due to chronic peptic ulcer, and the most effective method* of treatment of duodenal ulcer during the night hours.

London, W.1.

A. H. DOUTHWAITE.

EFFECT OF VITAMIN B_{12} ON ICHTHYOSIS

SIR,—Ichthyosis is a distressing condition, so I should like to report a chance observation.

A man, aged 69, recovering from a slight cerebral vascular accident, received injections of vitamin B_{12} ('Cytamen 50'), 50 µg. twice weekly, as a "tonic." He has had ichthyosis all his life. After about four injections the scaling appeared to be much reduced, and after ten injections few scales are left.

Is this a natural remission?

London, N.W.6.

W. LEVY.

PHARMACOLOGY OF ANTABUS

SIR,—The findings of Hine et al.,[1] quoted in your annotation of June 21, give, we feel, too simple an explanation of the pharmacological action of tetraethylthiuram disulphide ('Antabus').

In a similar investigation of 36 male patients recently *carried out at this hospital*, mild toxic side-effects of the drug have been repeatedly observed before any alcohol was given; in no case was there a corresponding increase of the acetaldehyde content of the blood. When a test dose of alcohol was given after the patient had had 1 g. of antabus daily for four days, the *severity* of symptoms corresponded with the blood-*acetaldehyde* level in three-quarters of the cases only. Slight reaction (flushing and tachycardia) was associated with an acetaldehyde level under 0·3 mg. per 100 ml.; moderate reaction (dizziness, nausea, headache, and fall in diastolic blood-pressure) with a level of 0·3–0·5 mg. per 100 ml.; severe reaction (fall in systolic and diastolic pressure and other signs of vasomotor collapse) with a level above 0·5 mg. per 100 ml.

No fewer than 9 patients behaved anomalously. In these, only slight reactions were associated with acetaldehyde levels of 0·4–0·8 mg. per 100 ml., suggesting that the production of acetaldehyde is not the only factor concerned. In our patients attempts to correlate these atypical reactions with age, body-weight, general

physical condition, and duration of addiction have been unsuccessful. Similarly, despite standardisation of the test procedure, we found the individual reaction unpredictable. The pharmacology of the drug being thus uncertain, the risk of accidents remains and must be guarded against.

HEXAMETHONIUM COMPOUNDS IN HYPERTENSION

SIR,—Dr. Blainey[1] concludes that "the hexamethonium compounds had not greatly lowered the basal blood-pressures," the basal blood-pressure being defined earlier on as that recorded in the morning before the patient rose. Moreover we are told that no night treatment was given.

It has been my experience, and that of others, that the hypotensive effect of hexamethonium lasts but a few hours (3–6), and it is only to be expected that no effect on the morning blood-pressure would be detectable.

Although it appears scientifically neat to put patients to bed for some time to assess the "true" level of their blood-pressure, what exactly are we proving? Merely that most hypertensives until a fairly late stage have labile blood-pressures. Surely we must regard as their real blood-pressure the figure with which they meet their daily problems, including a visit to the doctor, and not try to determine what nadir can be reached by subanæsthetic doses of drugs, as this figure gives us a false low level on which to base our studies. A few minutes' rest and reassurance in the consulting-room should be the basis for estimating pressures before and during treatment. It is important that at each visit the reading should be taken at the same time relative to the taking of the hexamethonium.

Bondi Junction,
New South Wales, Australia.
Z. FREEMAN.

SUCCINYLCHOLINE

SIR,—After reading the article by Dr. Evans and his colleagues (June 21) I should like to report on a case of protracted paralysis following the use of succinylcholine for closing the abdomen after an appendicectomy.

The patient was a woman, aged 56, weight 12 st., with no history of previous illness and who appeared to be perfectly healthy on preoperative examination. Pulse-rate 86 per min. Blood-pressure 140/85 mm. Hg.

11 A.M.—Anæsthesia was induced with 0·5 g. sodium thiopentone and 2 ml. gallamine triethiodide and continued with nitrous oxide, oxygen, and trichlorethylene. There was only momentary apnœa following the administration of the gallamine triethiodide.

11.25 A.M.—The appendix had been removed and for closing the abdomen, as relaxation was not adequate, 50 mg. of succinylcholine was given and the patient's lungs inflated with oxygen. There was immediate apnœa, which lasted 5 minutes.

11.30 A.M.—Respirations recommenced, 6 per min., shallow, and jerky.

11.35 A.M.—Respirations ceased completely.

11.40 A.M.—Operation completed. Artificial respiration continued. Pulse-rate 80. Blood-pressure 140/85, as at commencement of operation.

12 NOON.—Neostigmine 1·5 mg., atropine gr. 1/100 given intravenously with no effect.

12.15 P.M.—Picrotoxin given intravenously.

Artificial respiration was carried on during the afternoon.

6 P.M. (6½ hr. after the administration of succinylcholine).—The patient started to breathe in a spasmodic jerky manner, 5 per min.

7 P.M.—Respirations were re-established at 16 per min. Pulse and blood-pressure unchanged. Patient remained unconscious. Endotracheal tube was removed.

7.30 P.M.—Blood-pressure 80/40. Pulse-rate now 110. Respirations 18 per min. 'Methedrine' 15 mg. given intravenously.

8 P.M.—Blood-pressure 120/85. Pulse-rate 90.

8.15 P.M.—Patient transferred to the ward. Respirations 18 per min.

9 P.M.—Pupils reacted to light, equal.

9.15 P.M.—Movement of arms and legs when stimulated.

9.45 P.M.—Patient able to talk and move without difficulty.

The patient's general condition was excellent until 7 days later when her abdominal wound burst. On this occasion the anæsthetic consisted of 0·25 g. thiopentone, nitrous oxide, oxygen, and ether, from which she made an uninterrupted recovery.

This patient may have had a low serum-esterase, and the duration of apnœa was doubtless prolonged by the neostigmine which was given, although this was only given 35 min. after the administration of the succinylcholine. It is, however, difficult to explain the fact that shallow, jerky respiration at a rate of 6 per min. did commence 5 minutes after the dose of succinylcholine only to stop completely at the end of a further 5 minutes and spontaneous respirations did not return until 6 hours later.

This case occurred 3 months ago, and since then succinylcholine has been used in this hospital for abdominal relaxation without further trouble.

South London Hospital for Women and
Children, S.W.4.
M. L. MACKAY
Anæsthetic Registrar.

CONTROLLED HYPOTENSION

SIR,—I do not think your leading article of July 5 exhibits that high standard of impartiality which I have come to expect from THE LANCET. Thus I was surprised to find the work of Dr. Mackinnon cited in support of an impaired renal circulation during hypotensive anæsthesia, for such work is obviously of doubtful significance when applied to the anæsthetised patient. At the same time no mention whatever is made of the work of Miles et al.[1] who presented irreproachable evidence that a controlled hypotension induced by pentamethonium did not reduce the renal blood-flow in the anæsthetised patient. The observations of Dr. Bromage on macroscopic liver changes only support the contention, so often stated, that a pressure of 55–65 mm. Hg should be considered a minimum for this technique. These two papers do not provide evidence on which to base a criticism of this technique. Their information will help to produce at some future date a balanced and critical evaluation.

On the other hand, many will agree with you in accusing anæsthetists of using this technique on unsuitable patients, often with no adequate supervision of the induced hypotension. Such errors of technique and judgment have been responsible for many of the ill effects observed. A *controlled* hypotension practised strictly within the limits outlined by various workers[2] is a safe procedure.

No responsible anæsthetist will deny the difficulties of a controlled hypotension in certain patients. They realise that the technique demands constant care and attention to maintain safety. The hard work which this entails is forthcoming not because controlled hypotension is regarded as "modern" or "progressive," but because the patient receives benefits which are unobtainable by any other means.

London, W.1.
G. E. HALE ENDERBY.

SIR,—I would like to reply to Dr. Saunders's letter (July 5).

He implies that cerebral blood-flow is not reduced because the cerebral vasodilatation very nearly compensates for the fall in arterial pressure. If it is taken for

---

---

[1] Miles, B. E., de Wardener, H. E., Churchill-Davidson, H. C., Wylie, W. D. *Clin. Sci.* 1952, 11, 73.
[2] Griffiths, H. W. C., Gillies, J. *Anæsthesia*, 1948, 3, 134. Shackleton, R. P. W. *Brit. med. J.* 1951, i, 1054. Enderby, G. E. H. *Proc. R. Soc. Med.* 1951, 44, 829. Enderby, G. E. H., Pelmore, J. F. *Lancet*, 1951, i, 663.

granted that the same level of anæsthesia is maintained throughout, and therefore oxygen consumption by the brain is unchanged and the arterial oxygen saturation unchanged, then the above deduction is correct. However, the vascular supply of the brain has not been sufficiently explored to ensure that without doubt there is no alteration in vascular dynamics, such as, for example, an arterial shunt mechanism. If this were so the oxygen uptake by the brain could conceivably diminish with hypotension and mental deterioration take place without any change in cerebral venous oxygen content.

If we assume that there is no difference in cerebral oxygen metabolism (which cannot be measured unless total cerebral blood-flow is known) during hypotension, then, provided there is sufficient vasodilatation to compensate for the reduction in flow, cerebral functional activity will be unchanged; but once the limit of this type of compensation has been reached and the oxygen uptake by the brain falls, then cerebral anoxia will ensue. This critical level of hypotension will obviously vary with the amount of vasodilatation each individual is capable of, and is a factor difficult to assess before operation.

My experience is not entirely in agreement with Dr. Saunders's in that I have found a significant reduction in cerebral blood-oxygen under similar conditions. This work is not complete and certainly does not yet justify any firm conclusions.

Department of Anæsthesia,
University of Liverpool.

GOUGH HUGHES.

COOLEY'S ANÆMIA

SIR,—Dr. Choremis (July 5) states that he believes that "there is probably an ætiological relation between malaria and Cooley's anæmia."

One can accept this possibility in areas where malaria and Mediterranean anæmia coexist—for example, Italy. However, in New Haven, Connecticut, U.S.A., where there is a large population of Italian origin, Cooley's anæmia is not rare. The disease may be seen in second-generation Americans of Mediterranean origin, whilst malaria, on the other hand, is extremely uncommon. In these cases, it would be difficult to postulate any relationship between the two diseases. Incidentally, in these cases of Mediterranean anæmia in America the mongoloid facies were seen fairly often.

B. H. BASS.

POSTS FOR TRAINEE PATHOLOGISTS IN THE U.S.A.

SIR,—An acquaintanceship with physicians in your country has made it possible for me to place several young British doctors as trainees in American hospital laboratories. Requests from both sides of the Atlantic have increased in number, and I am now attempting to enlarge the exchange service which, I must emphasise, is completely unofficial. The members of the Horse Shoe Club, which has graciously admitted me to its honorary membership, will assist by screening, by interview, the English applicants; the club, of course, can assume no financial or other responsibility.

Should any of your readers seek trainee positions in laboratory medicine, they may write to me giving full particulars about themselves, and stating any geographical preferences in the States. I shall then endeavour to suit American laboratory and English candidate. It should be understood that the Horse Shoe Club is not to be addressed by the applicant.

At a time when coöperation between our countries is of such great importance, medical exchanges can play an important rôle.

Department of Pathology,
Saint Joseph Hospital,
Fort Wayne, 2, Indiana, U.S.A.

S. M. RABSON.

SEVERE RUBELLA

SIR,—Rubella is normally such a mild complaint that the following case seems worthy of note.

On July 2 the mother of a boy, aged $3^1/_2$, brought him to me with a slight morbilliform rash on the face, chest, and occipital regions. His temperature was 99°F; there were no Koplik's spots; occipital glands were enlarged. I told her that it was german measles and that she should keep the boy at home for a few days.

On July 5 she telephoned to say that he was very feverish. I found that his temperature was 102°F; there was a little bronchitis; the rash on the face was fading, but was quite bright on both legs. I gave an expectorant.

On July 7 the mother said that the boy had passed no urine for 24 hours. His face was puffy; there were fine crepitations over both bases; and the right eardrum was injected. I gave 'Distaquaine' penicillin 300,000 units. That night he passed 3 oz. of urine, which contained albumin+.

The following day his temperature was 99°F. His general condition was improved, and he passed more urine with only a faint trace of albumin in it. Penicillin was repeated.

On July 9 his temperature was normal, rash gone, and lungs clear. Two days later it was difficult to believe that he had been ill.

London, E.11.

SIDNEY ABRAHAMS.

FUNGUS INFECTIONS OF THE FEET

SIR,—I have read with interest your annotation of June 7 and the subsequent correspondence.

Silver nitrate in 10% aqueous solution, containing 5% rectified spirit, can confidently be recommended for all cases. It will be found especially beneficial in those that have failed to respond to other remedies. One application, followed by exposure of the lesions for a few minutes to direct sunlight, is usually sufficient; but two or three applications at daily intervals are sometimes needed in the tropics.

London, W.6.

ADRIAN V. ADAMS.

PREVENTION OF SEASICKNESS

SIR,—It was hardly fair of Dr. Gay (July 12) to criticise Glaser and Hervey's paper on seasickness,[1] which is too weak to stand up even with the most partisan support.

The rest of us have known since 1949 that some anti-histamine drugs are approximately as effective as hyoscine.[2] [3] If, two years later, Glaser and Hervey were to contribute anything useful they had therefore to make some more exact comparison between what were likely to be active drugs. One of the drugs they decided to compare with hyoscine was 'Phenergan,' preferring the opinion from two uncontrolled investigations[4,5] to that expressed by Chinn et al.,[6] after a carefully controlled trial, that it was one of the less active drugs. As Bethel[7] has already pointed out, they then gave it with such a timing that it could not be effective during the experiment. Similarly, they gave 'Benadryl' in half the dose used by Chinn,[8] whose report they cite.

Dr. Gay has already given his reasons for condemning the timing of the benadryl dosage; and they will find it difficult to defend their trials in rubber boats since it was known to Strickland et al.[9] in 1950 that 'Dramamine' could be ineffective in swing-sickness while active in airsickness.

ANATOMICAL NOMENCLATURE

SIR,—Professor Johnston's letter (July 5) indicates that British anatomists have at last decided to scrap the Birmingham revised (B.R.) terminology of 1933, which they have unsuccessfully endeavoured to impose on the medical profession in this country. As a student I had to learn two terminologies, known as the "Old and the New" (O.T. and B.N.A.). As a demonstrator I had to teach the B.R. terminology as well to the students, because the examinations were held in this terminology.

Professor Johnston is not proposing an innovation, but a welcome return to the B.N.A. which since 1895, and suitably modified with advance in knowledge, has enabled doctors of various countries to understand each other.

Barnstaple, Devon. MERVYN MOREL.

DIFFERENTIATION OF A.C.T.H. AND INTERMEDIN

SIR,—The observations of Sulman[1] on the colour change produced in *Hyla arborea*, the tree frog, following doses of preparations of A.C.T.H. have led to the contention that A.C.T.H. and intermedin are identical. Johnsson and Högberg[2], using *Rana temporaria*, support this contention. Recently, however, Geshwind et al.[3] have reported finding no correlation between the potency of A.C.T.H. preparations, measured by the ascorbic-acid depleting factor in rats, and the chromatophore response in *Rana pipiens*.

Morris[4] has drawn attention to the fact that A.C.T.H. is known to be rapidly destroyed by treatment with alkali, whereas the effect of intermedin is protected by such treatment; evidence also exists that intermedin and A.C.T.H. may be separated by electrophoretic and other procedures.[5]

Astwood[6] has postulated that different hormones may differently affect variously coloured chromatophores. *Xenopus laevis*, however, which possesses only melanophores, might be expected to give a less ambiguous response than species possessing other chromatophores. It was therefore thought that comparisons of the responses of hyla and xenopus might differentiate between A.C.T.H. and intermedin.

An A.C.T.H. fraction prepared from pig glands was treated by heating to 100°C for 10 minutes with N/10 NaOH, cooling, and neutralising. Treated and untreated material was given to the various test species as shown in the accompanying table.

EFFECT OF A.C.T.H. PREPARATIONS IN RAT, XENOPUS, AND HYLA

Species	Preparation*	Dose	No. of animals	Response	
Rat		*μg. per 100 g.:*		*Adrenal ascorbic acid (mg. per 100 g. tissue)*	
	A	15·0	4	475±15·4	
	B	1·5	4	357±35·0	
	Controls		4	490±28·0	
Xenopus		*μg. per 50 g.:*		*Melanophore index:*	
				1 hr.	*4 hr.*
	A	3·75	4	4·1	4·1
		1·87	4	3·0	2·8
	B	3·75	5	4·1	2·1
		1·87	5	2·7	1·9
	Controls		5	1·4	1·7
Hyla		*μg. per 5 g.:*		*Colour change 30 minutes †*	
	A	10·0	4	4/4	
		5·0	12	10/12	
		2·5	12	2·5/12	
		1·25	4	0·5/4	
	B	1·0	12	10/12	
		0·5	12	3·5/12	

* A = preparation treated with alkali. B = untreated preparation.
† A change to olive green was scored as 1·0, an intermediate change as 0·5.

These experiments show that when the adrenal ascorbic-acid depleting factor was almost completely destroyed by alkali, the potency to the chromatophore response in hyla was diminished about fivefold. On the other hand, the response of xenopus was quantitatively unchanged. The action was, however, prolonged (i.e., "protected") in both species. If the property of expanding the melanophores in xenopus is truly that of intermedin, these results indicate that: (1) hyla responds to both A.C.T.H. and intermedin; and (2) xenopus does not respond to A.C.T.H. and the response to intermedin is not influenced by the presence of A.C.T.H.

Further work is required to confirm whether these two species can reliably distinguish between the two factors in various hormone preparations and in body fluids.

PROVISION FOR THE MENTALLY DEFECTIVE

SIR,—Whilst it is possible to sympathise with Dr. Taylor in her difficulties with the parents of "educationally subnormal children," she has surely herself fallen into the very error against which she protests in her letter last week.

It has long been generally agreed that intelligence is distributed amongst the population in a continuous Gaussian curve, though with an actual ascertainment of numbers rather in excess of the theoretical expectation at the extreme lower end. Even so, the ascertainment of mental defectives of the feeble-minded class has been found to correspond very closely to the expected figure.

There is therefore no justification in making any distinction, other than an administrative one, between the "normal," the "educationally subnormal," and the "mentally defective." These three groups are all normal variations within the one human family. It is therefore scientifically incorrect—and, I might be allowed to add, morally shocking—to refer to the "stigma of mental defect." No such stigma exists, except in the minds of the ignorant or the prejudiced.

Those of us who spend our professional lives in the diagnosis, care, and treatment of mental defectiveness are surely entitled to expect that our colleagues should assist us in educating public opinion rather than in perpetuating ignorant prejudices by assuring the parents of "educationally subnormal children" that the "special schools" have nothing to do with "mental deficiency."

If Dr. Taylor doubts my facts, may I respectfully refer her to Prof. L. S. Penrose's *Biology of Mental Defect*?

Brockhall, Langho,
near Blackburn. D. J. ROSE.

BUTAZOLIDINE

SIR,—I am writing to confirm the findings of Dr. Currie and of Dr. Dudley Hart and Dr. Johnson (July 5) with regard to the use of butazolidine which I have administered in four cases.

The first was a woman, aged 45, with rheumatoid arthritis of long standing, without deformity but with swelling of the knees and wrists. She was in considerable pain, but she had had no previous treatment. She was given daily intramuscular injections of 5 ml. of a 20% solution of butazolidine, and the pain was very greatly eased and her general condition improved. A little residual pain was left in her knees but, as in the experience of the Westminster workers, the swelling remained the same.

The second case was a man, aged 52, who had had rheumatoid arthritis since 1933. He had considerable deformity of the elbows, fixation of the wrists, and limitation of movements of the knee. He had considerable pain and great difficulty in getting about. This patient had had much previous experience of therapy, having had many courses of gold, the usual anodynes, Spa treatment, and physiotherapy. He was started on butazolidine in May of this year and given a total of 50 injections (daily). After four days he reported that the pain was greatly eased; and though objectively the movement seemed to be the same, he stated that he had much more. The interest of this case is that the patient, with much previous experience of rheumatism therapy, volunteered that he had been helped by the butazolidine injections more than by earlier treatments.

The third case was a man, aged about 59, with rheumatoid arthritis; and he is still under treatment. He had had gold, physiotherapy, and anodynes, and volunteered that since he has had butazolidine movement has been much easier and that he feels better.

The fourth case has had only ten days' treatment, but the relief is so far the same as in the other three.

I am, of course, aware of the possible fallacies in estimating progress in rheumatoid arthritis; but this very small series includes three different types of case: (*a*) a case not previously treated, (*b*) a long-established case, and (*c*) two that may be termed "middle-grade." All these patients report improvement, and those with previous experience greater improvement than with any other form of treatment. At the moment I do not wish to do more than report these facts.

I am grateful to Pharmaceutical Laboratories Geigy Ltd., for a supply of butazolidine.

London, W.1. GERALD SLOT.

BREAD IN CŒLIAC DISEASE

IN his letter of May 3 (p. 928) Dr. Theodore James remarked that at the Duchess of York Hospital for Babies, Manchester, a diet for children with cœliac disease had been devised in accordance with the views of Dr. W. K. Dicke. This diet, which is free of wheat flour and gluten, includes bread with the following composition: 4 oz. cornflour, 4 oz. riceflour, 2 oz. glucose, 3 level teaspoons baking-powder, $^1/_2$ teaspoon salt, 1 egg, water to mix.

Put all dry ingredients together. Beat egg and add to remainder. Mix to a soft paste with water. Put into greased pie-dish. Bake in hot oven, reg. 7, until set (about 10 min.); then finish at reg. 2, until cooked. Total time about 25 min.

Medicine and the Law

The Prescription of Barbiturates

DURING a recent inquest at Doncaster, Dr. F. G. Tryhorn, director of the Forensic Science Laboratory at Wakefield, told the coroner that three-quarters of the deaths with which the laboratory dealt turned out to be due to phenobarbitone poisoning.

The inquest, reported in the *Manchester Daily Dispatch* (July 2), was upon the death of a widow, 79 years of age, who was said to have left a note stating that she had taken 150 tablets. There was evidence that she had taken at least 120 grains and that about 30 grains would be a fatal dose. A policeman said that he found in her house six boxes containing hundreds of tablets. The coroner expressed the view that there was too much laxity in prescribing the drug. It was prescribed, he thought, for "any sort of trouble" and doctors were often "not strong enough to resist when patients demanded more"; there should be more control. A verdict was returned of suicide while the balance of her mind was disturbed.

At another Doncaster inquest, on a woman of 35 found dead in her bath, Dr. Tryhorn said that there were 15 grains of an unidentified barbiturate in her blood-stream. Though this was a larger amount than would be prescribed, it would not be a suicidal dose. He agreed with the coroner that such drugs should not be taken before having a bath. There being no evidence of suicide, a verdict of death by misadventure was returned. In this case also the coroner commented on the need to control prescription of the drug.

Dr. R. W. L. Ward, secretary of the Doncaster branch of the British Medical Association, subsequently replied to these criticisms when interviewed by a correspondent of the *Yorkshire Post* (July 2). He thought the risk had been somewhat exaggerated. It had been stated at the first of these two inquests that barbiturate drugs were now prescribed as freely as were aspirins twenty or thirty years ago. He could not agree with the statement. These drugs were extensively used in treating high blood-pressure, which was increasingly diagnosed; they were used even more freely in the United States. He was unaware of the circumstances of the particular case, but some patients had to have barbiturate drugs over a very long period. A stock could easily be built up by a patient intent upon suicide.

Parliament

Prescription Charges

IN the House of Commons on July 11, replying to the motion for the adjournment, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said the difficulties of collecting the shilling charge for prescriptions had been much exaggerated. In the experience of three large London hospitals—the London Hospital, Hammersmith Hospital, and the Royal Free Hospital—only one outpatient had been unable to pay the shilling. There had been a small increase in quantities prescribed, but as the charge had only been in operation for a month she would not like to say the figure was firm. On the limited survey they had been able to make the number of items per form had *risen from 1·57 to 1·7. From an assessment made in* a limited number of areas the falling off in the number of prescriptions seemed to be under 15%.

QUESTION TIME

Hospital Beds for Mental Defectives

Mr. B. R. BRAINE asked the Minister of Health the total number of beds set aside for mental defectives in each hospital region in England and Wales; the number of such beds occupied; and the number of persons awaiting admission, showing, separately, adults and children.—Mr. IAIN MACLEOD replied: The figures are given in the table. Column 2 shows how many beds ought to be provided, on standard, in space available; column 3 shows the number of beds which could be made available if staff could be found for them; this shortage of staff exacerbates the overcrowding; *column 4 shows the number of beds actually in use. The waiting-list figures are taken from returns from local health authorities, whose areas sometimes fall in more than one region; in the latter cases the lists have been apportioned to regions in ratio of the populations of the local authority areas:*

Region	Recognised bed space for mental defectives (2)	Beds in wards not in use (3)	Number of patients occupying beds (4)	Number awaiting admission	
				Adults (5)	Children (6)

Fluorination of Water-supplies

MR. S. P. VIANT asked the Minister of Health which were the interested bodies represented on the mission which had visited the United States of America to examine American investigations into fluorine in water; whether the report of the mission would be made public; and whether the detailed evidence on which they formulated their report would also be published.—Mr. Macleod replied: The members of the mission were Miss Jean Forrest, L.D.S., dental officer, Ministry of Health; Mr. J. Longwell, D.SC., Government chemist's department; Prof. H. H. Stones, M.D., F.D.S. R.C.S., member of the Dental research committee, Medical Research Council; Dr. A. M. Thomson, nutrition research team, department of midwifery, University of Aberdeen. The question of publication will be considered when I have received the mission's report.

Obituary

JAMES OWEN DAVID WADE

O.B.E., M.S. Lond., F.R.C.S.

Mr. James Wade, who died on July 9 at the age of 66, had been senior surgeon at Cardiff Royal Infirmary for ten years, and it was only towards the end of last year that he retired from the active staff.

He began his medical studies in Cardiff and continued them at Charing Cross Hospital, graduating M.B. in 1909. After taking the F.R.C.S. in 1912 and the M.S. in 1913 he returned to Cardiff, where he was soon appointed to the staff of the infirmary. He began to demonstrate anatomy at the University College of South Wales as well as practise surgery. Throughout his life he retained his interest in anatomy, and after he retired he helped in the department of anatomy of the medical school. During the 1914–18 war he was consulting surgeon at the Prince of Wales Hospital for Limbless Soldiers and Sailors in Cardiff, and for this work he was appointed O.B.E.

L. R. writes: "Never in the best of health, 'Jimmy Wade' was none the less a great worker and he never spared himself; indeed many of his friends wondered that he was able to do so much and for so long. He was a good surgeon, in great demand both in Cardiff and the surrounding valleys and travelled much doing long lists of operations in many and various hospitals. A kindly man with a reassuring presence, a pleasant smile, and a cheerful countenance, he was a philosopher in his own way and he persuaded many a young man to give up chasing the *ignes fatui* and seek the substance rather than the shadow. He was a fighter, and would laughingly complain of a cold wind which made him short of breath; and above all he was a splendid family man devoting his life to his wife and sons, one of whom has succeeded him as a surgeon on the staff of the Royal Infirmary, while the three others are members of his and our profession. It was always good to see Jimmy Wade; one was the better for it; and at a time of controversy, which was sometimes heated, and when there was some ill feeling, his detachment and cheerful outlook and confidence in the things that matter, was an encouragement to many."

Births, Marriages, and Deaths

BIRTHS

Heron.—On July 10, at Little Place, Middleton, to Jean (née Bland), wife of Dr. Geoffrey Heron—a son.

Mackintosh.—On July 5, at Dunsfold, Bramhope, near Leeds, to Eileen (née Ormsby Johnson), wife of Dr. F. G. Mackintosh—a daughter.

Nelson.—On July 5, at Stourbridge, to Barbara, wife of Dr. Alastair Nelson—a daughter.

Reeks.—On July 2, at Windermere Nursing Home, Paignton, to Louise (née Atkinson), wife of Dr. J. J. Reeks—a daughter.

MARRIAGES

Hardy—Gosling.—On July 8, at Edgbaston, Hugh Nevill Hardy, B.M., to Mary Rose Gosling, of Edgbaston.

Woodmansey—Junor.—On June 30 at Benenden Church, Kent, Arnold Colin Woodmansey, M.D., B.SC., D.P.M., to Faith Junor M.A.O.T.

DEATHS

Atkins.—On July 7, John Francis Atkins, M.B. Birm., of Hove.

Benson.—On July 7, at Morchard-Bishop, Crediton, John Robinson Benson, F.R.C.S., aged 83.

Budden.—On July 4, at Greywell, Hants, Rev. Charles William Budden, M.A., M.D. Vict. Univ., aged 74.

Falkener.—On July 5, Lyon Falkener, M.A., M.D. Camb., D.P.H., of La Marette, Guernsey, aged 85.

Hulbert.—On July 4, in Ealing, Ernest Beddoe Hulbert, M.D. Durh.

Kirkpatrick-Picard.—On July 10, at Burgess Hill, Sussex, Arthur William Kirkpatrick-Picard, M.D. Lond., aged 83.

MacLaren.—On July 8, at Odstock Hospital, Salisbury, James Alexander MacLaren, M.D. Manc., aged 82.

Diary of the Week

JULY 20 TO 26

Tuesday, 22nd

Royal College of Surgeons, Lincoln's Inn Fields, W.C.2
4 P.M. Prof. R. R. Macintosh: Anæsthesia in Dental Surgery. (International Dental Congress lecture.)

Wednesday, 23rd

Institute of Psychiatry, Maudsley Hospital, Denmark Hill, S.E.5
8.15 P.M. Dr. Harold G. Wolff (New York): Headache Mechanisms.

Thursday, 24th

Royal College of Surgeons
4 P.M. Dr. W. S. McConnell: General Anæsthesia in the Dental Chair. (International Dental Congress lecture.)

Friday, 25th

Medical Society for the Study of Venereal Diseases, 11, Chandos Street, W.1
7.30 P.M. Dr. R. A. Nelson: Changing Concepts in the Serological Diagnosis of Syphilis—Wassermann Reagin Versus Specific Treponemal Antibody.

Saturday, 26th

Medical Society for the Study of Venereal Diseases
2.30 P.M. (St. Mary's Hospital, Paddington, W.2.) Dr. Herman Beerman (University of Pennsylvania): Cardiovascular Syphilis.

Appointments

Beech, John, M.B. Sheff., D.M.R.: asst. radiotherapist, radiotherapy centre, Derbyshire Royal Infirmary.

Blair, J. D., M.B., B.SC. Glasg., D.A.: asst. anæsthetist, Grimsby General Hospital, and Louth County Infirmary.

Durkin, Sheila, M.B. Aberd., D.P.H.: asst. M.O.H. and asst. school M.O., Smethwick.

Knowlson, Lydia, M.D. Leeds, D.P.H., D.C.H.: senior M.O. for maternity and child welfare for Monmouthshire.

Colonial Service:

Ahearne, Mary, M.B. N.U.I.: M.O., Nigeria.
Alvares, R. E., M.B. Hong-Kong: pathologist, Hong-Kong.
Barman, D., M.B.: M.O., Malaya.
Bryson, A. F., M.B. Camb., F.R.C.S.: senior orthopædic specialist, Nigeria.
Coghlan, C. T., M.B.: M.O. (anæsthetist), Kenya.
Gilchrist, K. J., M.B. Lond., F.R.C.S.: surgeon specialist, Fiji.
Griffiths, P. G., M.C., M.B. Manc., M.R.C.P., F.R.F.P.S.: physician specialist, Malaya.
Hing, E. W. Lou-, L.R.F.P.S.: M.O. (Grade C), Trinidad.
Hoar, C. E. W., M.B. Lond., D.C.P.: pathologist, Uganda.
Joly, J. S., M.B. Camb., F.R.C.S.: surgeon specialist, Trinidad.
Keeley, Russell, M.B.: M.O., Malaya.
Khaira, B. S., M.B.: M.O., Malaya.
Kraszewski, T. M., M.B., Polish School of Medicine, Edin.: M.O., Sarawak.
Mackie, J. B., M.B. Edin., D.P.H., D.T.M.: senior specialist, Hong-Kong.
Ndukwe, D. O., L.R.C.P.I., D.P.H.: M.O.H., Nigeria.
Richardson, R. K., M.R.C.P.: senior physician, British Guiana.
Slawinski, Karol, M.D. Beirut: M.O., Malaya.
Taylor, J. M., M.B.: M.O., Malaya.
Twomey, John, M.B. N.U.I.: M.O., Somaliland Protectorate.
Wilkinson, P. B., M.B. Lond., M.R.C.P.: senior specialist, Hong-Kong.

South-East Metropolitan Regional Hospital Board:

Cowie, T. N., M.D., B.SC. Glasg., D.M.R.D.: consultant radiologist, Woolwich, Greenwich, and Deptford group.
Ross, D. F., M.B. Aberd., D.M.R.D.: consultant radiologist, Hastings group.
Stamp, G. F., M.B. Birm.: asst. physician (geriatric services), Orpington and Sevenoaks, and Bromley group.

The Hospital for Sick Children, Great Ormond Street, London:

Batten, R. L., M.R.C.S.: house-surgeon.
Davies, H. E. F., M.B., B.SC. Lond.: house-physician.
Davies, O. W., M.B. Lond.: house-surgeon.
Dobson, J. R. E., M.B. N.Z., D.P.M.: part-time registrar to the department of psychological medicine.
McRobert, Catherine, M.B. Madras: asst. resident M.O., Tadworth Court.
Wells, Joan, M.D. Lond., M.R.C.P.: house-physician.

Welsh Regional Hospital Board:

Bevan, Beryl, M.B., B.SC. Wales: asst. M.O. (S.H.M.O.), Blood Transfusion Service, Cardiff.
Recht, W. C., M.D. Prague, F.R.C.S.E.: asst. orthopædic surgeon (S.H.M.O.), Newport and East Monmouthshire H.M.C.
Stephens, B. J., M.D. Lond.: consultant pathologist, St. David's Hospital, Cardiff.
Wowkonowicz, C., M.B., D.M.R.D.: asst. radiologist (S.H.M.O.), Caernarvon and Anglesey H.M.C.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Notes and News

AN INTERNATIONAL SEMINAR ON MENTAL HEALTH

CLOUDY and speculative as much of our information must be, as yet, on the development of the mind and emotions, we have begun to master some of the key patterns in early behaviour and to find some practical rules for promoting mental well-being and avoiding gross emotional harm to the infant and young child. Some of this knowledge could be used at once if it were widely enough disseminated, and the World Federation for Mental Health have long been considering effective ways of spreading it.

As an experiment, this year, they are holding an international seminar on "Mental Health and Infant Development" at the Bishop Otter Training College, Chichester, from July 10 to Aug. 10. This will be a pilot run for future seminars, and is perhaps the forerunner of one, or even several, international institutes with continuous programmes of research and education.

Many national and international bodies have contributed generously to the expenses of this initial project, and the World Health Organisation, through its European regional office, has awarded fellowships to enable 38 Europeans to attend, and has offered technical services up to a value of over £3000. Through its other offices it is helping fellows to attend from other parts of the world. UNESCO, the National Advisory Mental Health Council of the U.S. Public Health Service, the International Children's Centre of Paris, and the Grant Foundation of New York have all given generous help.

Both the participants and the faculty will be learning from this new venture; but the faculty, a distinguished body of psychiatrists, psychologists, anthropologists, pædiatricians, and public-health and psychiatric social workers, will be there to share their experience with others and join in a group experiment in techniques of learning. The programme will cover child development patterns, comparative studies of case-material in North America, Great Britain, and France, and their relation to similar material in less developed countries, and the practical application of these studies.

CAR-DRIVERS WITH DEFECTIVE VISION

THE council of the Faculty of Ophthalmologists has issued a statement urging doctors to keep in mind the danger of visual disabilities in people driving motor vehicles. The statement continues: "Although the legal restrictions for driving refer only to defects in central vision there are potential dangers in other visual defects, such as night blindness and gross restriction of the visual fields. Patients suffering from such defects should either be warned about the need for care in driving, or (if the defect is serious) they should be emphatically advised not to drive at all."

RESEARCH IN DAIRYING

MUCH of the work at the National Institute for Research in Dairying is of interest to those concerned with health and disease in man. Much of it, too, is fundamental. A foreword to the report for 1951[1] observes: "This is the result of a deliberate policy, since it has been found, in practice, that if the whole of the time of a research department is given to the solution of urgent technological problems and no time is given to fundamental ones, that department tends to lose touch with new developments of scientific thought, and lags behind in the application of modern research methods and devices. As a result its ability to tackle even the *ad hoc* problems of the industry tends to diminish."

Nevertheless the report deals partly with work of immediate practical importance. Thus feeding experiments have confirmed that pigs reared indoors benefit from the addition to their diet of a small quantity of liver extract, and that, irrespective of treatment, animals reared out of doors grow better than those reared indoors. Evidence has been gathered, too, that for fattening pigs fed on a basal diet containing white fish meal, supplementary aureomycin mash, aureomycin itself, or penicillin promotes growth slightly; and when the basal diet is restricted to vegetable protein only, the addition of antibiotics and antibiotic residues enhances growth considerably—at least to the level obtained with a diet containing animal protein but no antibiotic. From studies of the œstrogen content of grassland herbage, undertaken in conjunction with the Courtauld Institute of Biochemistry, Middlesex Hospital, London, it now seems that plants contain more than one such active substance. The possibility that the œstrogen in leaf is associated with chloroplasts and that another œstrogen is associated with the more widespread cytoplasmic protein is being explored.

A NEW LEEDS JOURNAL

THE first issue of the *University of Leeds Medical Journal* contains an impressive group of articles on tuberculosis. In the first of them Dr. F. Ridehalgh ascribes the reduction of the tuberculosis death-rate during the past century mainly to social legislation and changes rather than medical care; but he believes that effective diagnosis, better case-finding, the development of antibiotics, and efficient units of thoracic medicine and surgery should accelerate the decline in mortality, and he lays stress on the need for proper support of the family in which the breadwinner falls ill. "Any measure," he says, "which maintains the standard of health and nutriment of a tuberculous family will ultimately be reflected in a fall in the total number of cases of tuberculosis." Other articles deal ably with the early diagnosis of phthisis, tuberculosis in childhood, radiological appearances, bone and joint tuberculosis, tuberculosis of the skin and glands, tuberculous meningitis, the surgery of pulmonary tuberculosis, sanatorium treatment, and the treatment of tuberculosis of the genito-urinary tract. Such an ambitious and capable first issue bodes well for the future, and we wish the new journal success. It is the lineal descendant of the *University of Leeds Medical Society Magazine*, by way of the *University of Leeds Medical Magazine*. From 1931 onwards these, like the tuberculous family, in turn strove with financial hardship and somehow managed to carry on. The stock is evidently tough.

BUCKSTON BROWNE DINNER

AT the Buckston Browne dinner, held at the Royal College of Surgeons of England on July 8, Miss Patricia Hornsby-Smith, in proposing the toast of The College, thanked her hosts for the help which the college had given the Ministry of Health in developing the National Health Service. The college, she continued, had been largely built by the faith of the medical profession, and many of the new consultants in the National Health Service owed their skill to facilities provided by endowments such as that provided by the patron of the evening, Buckston Browne. Through the generosity and foresight of past surgeons the college was today able to sustain new advances in its specialty. It had always shown itself ready to move with the times, and in particular it had constantly fostered imperial ties in surgery. Today Lincoln's Inn Fields was famous as a scientific and social centre of surgery throughout the whole world.

Sir Cecil Wakeley, F.R.C.S., began his reply by congratulating Buckston Browne's son-in-law, Sir Hugh Lett, on the jubilee of his fellowship. Turning to the customary annual presidential review he said that the most important event of the year had been the acceptance by Her Majesty the Queen (when Princess Elizabeth) of the honorary fellowship. The rebuilding of the college had started, and the erection of the first steel work was due to begin next month. The college was grateful to all subscribers to the restoration fund, not least to Sir Montague Burton, the most generous of its recent donors. But finance, Sir Cecil confessed, was an uneasy subject; for the college, like most institutions of its kind, suffered from a chronic difficulty in making ends meet. Indeed unless a substantial new source of income were found ends would be a long way apart when there was need to maintain buildings about twice the size of the present ones. With this difficulty in mind the council was seriously considering levying an annual subscription from all new fellows admitted in future. But the college, he ended, continued "mindful of tradition and the lessons of the past, lively in the affairs of the present, and poised alert on the springboard of further endeavour."

Mr. P. H. Mitchiner, the senior vice-president, welcomed The Guests to an occasion which he said their founder had insisted should be a family party. Mr. Justice Danckwerts, though he explained that as a Chancery Judge he was not supposed to know much about life, replied urbanely for his fellow guests and himself.

University of London

At a recent examination for the academic postgraduate diploma in bacteriology the following were successful:

A. J. Beale, Aleck Bernstein, Svarna Lata Bhatia, Catherine M. P. Bradstreet, J. G. Brotherston, E. R. N. Cooke, Minnie K. Herring, Ma Hpay, M. H. Hughes, E. M. Mackay-Scollay, P. G. Mann, Kazi Abul Monsur, W. R. Parry, D. J. Ross, J. M. Talbot.

University of Liverpool

At recent examinations the following were successful:

M.D.—N. J. Gourdji, Helen T. Morgan, G. R. Wadsworth, D. C. Watson, A. S. Whitehead.

Final examination for M.B., Ch.B.—D. W. B. Woolven (first-class honours), R. J. Fallon, Irene M. Irving, W. G. Lamberd (second-class honours); Margaret M. Ashcroft, A. C. Beeby, F. Berry, A. S. Binnie, J. S. Birch, Elizabeth Bownass, N. H. Brodie, J. M. Brown, J. W. Brown, T. Bury, E. P. Carrigan, D. A. P. Cooke, W. E. Cooper, G. Corney, Enid C. Davies, J. C. Denmark, A. J. Entwistle, R. H. Fitzgerald, W. D. Fitzsimons, Mary I. Gibbons, A. E. Goetzee, L. V. Gould, K. Grainger, P. W. Green, S. J. Hargreaves, F. B. Hartley, Margaret H. Hellaby, N. St. J. Hennessy, Barbara M. Hitch, S. H. Hoddes, J. Hogan, R. P. Hoskinson, E. M. Hughes, G. Ingram, Brenda Jones, Winifred E. Jones, P. P. Keith, Jean Knowles, A. M. Laylee, D. G. G. McLeish, Maureen E. Murphy, A. Nixon, G. Park, F. P. Peach, G. C. S. Roberts, V. Rogers, H. G. Row, A. Sandieson, A. C. Saunders, S. J. Surtees, T. E. Tasker, P. G. Vivian, E. S. Watkins, W. A. Weston, A. H. Wilde, Mary P. K. Williams, P. H. Wright.

D.P.H.—M. S. Boparai, D. Brabott, J. L. Cotton, Angelika Haider, Hla Han, Na Ayudhia V. Israngura, N. N. Kanyarutoke, A. R. Kennedy, E. Lutfi, Lillie L. Munro, R. C. O'Gray, W. H. Parry, E. F. W. Richards, T. A. J. Thorpe, K. O. Torgersen, P. H. Waage.

D.M.R.-D.—F. G. Anderson, W. E. C. Astle, E. Walker, J. K. Walker.

University of Sheffield

Dr. E. H. Gillespie has been appointed honorary lecturer in bacteriology, and Dr. I. J. MacQueen and Dr. R. S. Sneath demonstrators in anatomy.

University of Glasgow

On July 5 the following degrees were conferred:

M.D.—T. D. V. Lawrie, Nanette H. Nisbet, and J. G. Stevenson (with high commendation); John Harkness and I. W. MacPhee (with commendation); John Simpson.

M.B., Ch.B.—J. H. Adams, T. G. Anderson, R. L. Andrews, T. W. Baillie, I. A. Bowie, K. D. Boyd, Marion S. Boyd, T. I. Boyd, R. T. Boyle, Janet C. Brash, P. I. Brown, W. M. Buchanan, A. I. Burleigh, Thomas Cairns, A. R. Cameron, Donald Campbell, E. C. Campbell, Roderick Campbell, W. M. Campbell, A. C. Cattanach, Denis Cavanagh, Thomas Chalmers, Thomas Christie, Henry Church, W. G. Clark, J. G. Clarkson, John Cleat, Anne M. Cormack, T. C. Coyle, John Diamond, Elspeth S. Dickie, J. D. Dickson, T. H. P. Dippie, J. R. Donald, J. M. Dubé, H. L. Duthie, Carl Edwards, J. R. Evans, J. S. Ferguson, J. A. L. Finch, G. S. Findlay, J. S. Findlay, D. H. Finlayson, D. J. B. Fletcher, N. C. Frame, W. T. Frame, G. A. Garrick, A. B. N. Gilfedder, David Glover, A. G. Graham, T. D. Grant, Sheila C. Gray, W. M. Gray, A. B. Gwan-Nulla, K. H. Haddow, T. G. Haddow, Isabel W. Haldane, William Hamilton, Sheila C. A. Stewart, D. Y. M. Hart, W. M. Hay, P. J. Hilley, Doreen L. Ireland, Arthur Jamieson, G. M. Johnstone, D. L. B. H. Jones, Herbert Kay, Denis Keown, W. G. Kilpatrick, D. M. Kirkwood, T. D. Lightbody, W. J. Lockie, Marjorie C. E. MacBeath, I. N. McCulloch, John McDonald, W. M. McFarlan, William McIntosh, Margaret Macintyre, J. R. McIver, Jean M. MacKay, G. B. McKelvie, A. M. MacKenzie, A. F. F. McLean, E. S. MacLean, J. W. McLellan, K. K. MacLeod, James McMichael, R. M. Macneill, G. P. McNicol, F. T. MacVicar, H. K. Mason, Sheila M. Y. Maxwell, P. E. Michaelides, J. B. Mitchell, J. H. Mitchell, W. C. Moffat, D. D. Moir, Donald Montgomery, Sasha R. Morris, M. S. Muir, I. P. C. Murray, George Neilson, D. H. Nimmo, Helen B. O'Hea, A. M. Orcharton, S. H. R. Palmer, Thomas Park, Ian Paterson, John Rankin, Ruth I. Rankin, Robert Rankine, M.A., I. O. Roxburgh, J. S. Roxburgh, James Ruffell, I. S. Scott, K. B. Scott, Ralph Shulman, J. A. Smith, R. A. Stark, Margaret P. D. Steen, W. A. Stevenson, I. G. Stewart, J. G. Stewart, R. C. Taylor, Ann R. Templeton, James Terendale, Anne C. E. Thompson, Mary F. Thomson, G. C. Timbury, A. P. Walker, F. C. Walker, W. H. R. Waters, J. R. Watson, W. A. K. Weir, J. W. Whitelaw, B. F. Whiteley, Christian F. Whyte, A. C. Wilson, Audrey M. S. Wilson, D. G. Wilson, William Wilson, H. L. C. Young, J. M. H. Young.

At a recent examination for the D.P.H. the following were successful:

Elspeth V. Beveridge, J. M. Boyd, D. H. Cawith, Mary E. Hamilton, J. H. Henderson, Ella Macdonald, Max Park, J. J. Prag, H. K. Rose, Hope B. T. Scott, A. G. Sked, W. D. Wilson.

National University of Ireland

On July 8 honorary degrees were conferred on medical men as follows:

LL.D.—Prof. E. P. McLoughlin, Dr. A. W. S. Sichel, Prof. Edward Keenan, Prof. Charles O'Malley.

D.Lit.—Mr. William Doolin, Senator Henry Barniville.

D.Sc.—Sir Henry Cohen (in absentia), Sir John Parkinson, Prof. Stephen Shea, Prof. James O'Donovan.

M.D.—Major P. J. Delaney, Sir Stewart Duke-Elder, Sir John McNie, Dr. Angus Macrae, Prof. Patrick Kiely, Dr. Francis Lavery, Prof. Henry Moore, Prof. John McGrath.

M.D.S.—Prof. James O'Connor.

University of Leeds

Dr. C. L. Oakley has been appointed to the Brotherton chair of bacteriology in succession to Prof. J. W. McLeod who is retiring.

Dr. Oakley, who was born in 1907, graduated in medicine from University College Hospital, London, and in science from Chelsea Polytechnic in 1930. During the next three years he was Graham scholar at University College Hospital Medical School where he studied liver pathology and the regulation of marrow activity. In 1933 he took his M.D., and the following year he was appointed experimental pathologist at the Wellcome Research Laboratories at Beckenham, where he did work on virus diseases. Later with Dr. G. H. Warrack and others he turned his attention to the soluble antigens of the pathogenic clostridia. During the late war he was in charge of a subsidiary unit of the Beckenham Laboratories which produced antitoxins for the Army. In 1947 Dr. Oakley became head of the immunology and experimental pathology department at Beckenham. He was elected a fellow of University College in 1950. In his most recent work on the sites of origin of antibodies he has demonstrated that, in rabbits, injection of alum-precipitated diphtheria or tetanus toxoid into skin, fat, or muscle leads to local production of specific antitoxin.

Royal College of Surgeons of England

At a meeting of the council held on July 10, Sir Cecil Wakeley was re-elected president for the ensuing year. Sir James Paterson Ross and Sir Reginald Watson-Jones were elected vice-presidents. Sir Clement Price Thomas, Mr. C. Naunton Morgan, Mr. Hedley Atkins, and Mr. Myles Formby were admitted as members of the council, and Dr. O. C. Carter (representing general practice) and Dr. Bernard Johnson (representing anæsthetics) were coöpted to the council for 1952–53.

Mr. F. McGuckin (Newcastle) was admitted to the fellowship ad eundem, and Mr. A. J. Boase (Uganda) as a member of 20 years' standing.

Prof. Gilbert Causey was admitted as the Sir William Collins professor of human and comparative anatomy. Dr. D. R. Lucas was appointed research pathologist to the ophthalmological research unit. A Macloghlin scholarship was awarded to Brian Greenwood of Halifax.

The following lecturers were appointed:

Hunterian professorships.—Prof. Naguib Makar Bey, Pathogenesis of Cancer in the Bilharzial Bladder; Mr. Terence Cawthorne, Surgery of the Temporal Bone; Mr. Wilfred Hynes, Pharyngoplasty by Muscle Transplantation in Failed Cleft Palate Cases; Mr. R. F. Phillips, Neuroblastoma; Mr. K. W. Starr, Acute Postoperative Dilatation of the Stomach; Mr. Rodney Smith, Pancreatic Neoplasms; Mr. J. E. Richardson, Early Renal Symptoms of Parathyroid Tumour; Mr. James Moroney, Colonic Replacement and Restoration of the Human Stomach; Mr. J. B. Wyman, Use of Pentamethonium and Hexamethonium Salts in Major Surgery; Mr. Douglas Jackson, Burns; Mr. G. K. Tutton, Cerebral Abscess; Mr. H. H. G. Eastcott, Arterial Grafting for the Ischæmic Lower Limb; Mr. S. S. Rose, Cases of Recurrent Swellings of the Salivary Glands; Mr. F. A. Henley, Gastrectomy with Replacement; Surgeon Commander Frank Ellis; Mr. Paul Brand.

Arris and Gale lecturers.—Mr. Cedric J. Longland, Collateral Arterial Circulation in the Limb; Mr. A. A. G. Lewis, Control of the Excretion of Water by the Human Kidney; Mr. H. F. Lunn, High Ligation of the Neck of the Sac in Inguinal Hernia; Mr. L. P. Le Quesne, Water and Electrolyte Administration during the Postoperative Period.

Erasmus Wilson demonstrators.—Mr. Philip H. Mitchiner; Dr. L. W. Proger, Dr. Magnus Haines.

Arnott demonstrators.—Mr. Mitchiner; Prof. Lambert C. Rogers Mr. Frank Stansfield; Prof. R. J. Last.

The following diplomas were granted, jointly with the Royal College of Physicians:

D.L.O.—A. G. Ackerley, E. C. Atkinson, Sushil Chandra Banerji, J. S. Brown, B. W. M. Bushell, P. P. Clifford, Frank Fleming, A. W. Halfhide, Savitri Itchhaporia, H. B. Juby, Kershaw Burjor Khambatta, E. H. Ross, G. E. Rousseaux, P. R. McH. Scales, Rama Heramb Prasad Sinha, T. C. Taylor, P. H. Wood.

D.P.M.—J. S. Dawson, Aleck Folkson, David Glendinning, Nest Kahan, G. A. Levinson, G. S. Mansell, Hyman Rosenberg.

D.A.—R. J. H. Hodges.

D.T.M. & H.—H. P. M. Perera, R. T. Scholes.

Royal Australasian College of Physicians

At the annual meeting of the college held in Adelaide in May, 1952, with Dr. Alex Murphy, the president, in the chair, the following were elected to the fellowship:

C. G. Bayliss, J. H. Colebatch, K. J. Grice, W. E. King.

The following, having satisfied the boards of censors in Australia and New Zealand, were admitted to the membership:

J. L. Allsop, A. L. Anderson, G. E. Bauer, D. A. Ballantyne, B. P. Billington, J. V. Cable, R. G. Dreadon, A. A. Ferris, J. J. Fitzwater, A. J. Goble, C. Gresson, P. F. Hall, D. A. Henderson, K. H. Holdgate, C. W. Howden, J. D. Hunter, I. R. Mackay, T. G. Maddison, J. W. Perry, D. W. Piper, V. E. Sampson, G. Selby, B. C. Sinclair-Smith, I. D. Thomas, A. R. Tink, D. Tomlinson, A. S. Turner, R. H. Vines, C. E. Watson.

The diplomas of F.R.A.C.P. and M.R.A.C.P. have lately been given recognition by the General Medical Council.

Society of Physicians in Wales

This society, which was founded a year ago, held its third meeting at Swansea on June 27 and 28, under the chairmanship of Dr. Esmond Rees. Papers were read by Prof. Harold Scarborough, Dr. J. M. Swithinbank, Dr. Leonard Howells, Dr. Philip Evans, Dr. J. D. Spillane, and Dr. F. L. Dyson. In future, meetings will be held annually, and it is proposed to hold the next in North Wales on June 26 and 27, 1953. The hon. secretary of the society is Dr. Leonard Howells, 71, Cathedral Road, Cardiff.

Congress of Therapeutics

The third International Congress of Therapeutics is to be held in Madrid from Oct. 16 to 18. The main subjects chosen for discussion are Potassium, Massive Hormone Therapy, and Radio-isotopes. The speakers will include Dr. A. S. Macfarlan and Dr. Eric Pochin. Further particulars may be had from the secretariat of the congress, Instituto de Farmacologia, Ciudad Universitaria, Madrid, Spain.

Infantile Paralysis Fellowship

The first welfare conference of the fellowship, which was held in London last month, was attended by delegates from nearly all of the fellowship's 40 branches in the British Isles. The conference was addressed by Mr. Greaves, a local officer of the National Assistance Board, and by Mr. Dalby, a group disablement resettlement officer of the Ministry of Labour. The address of the fellowship is Rugby Chambers, Great James Street, London, W.C.1.

A Conference on Loyalties

At a meeting to be held in Oxford from Aug. 2 to 9 the Present Question Conference, founded in 1945, will discuss Conflicts of Loyalties. The programme may be had from the secretariat at 37, Middleway, London, N.W.11.

A New Antibiotic

The discovery of a new antibiotic, named 'Ilotycin,' has been announced by Messrs. Eli Lilly and Company. This drug, which is still in the experimental stage and is not yet generally released, has a broad spectrum and has proved effective against certain organisms which have developed resistance to penicillin or other antibiotics. It can be given by mouth.

West London Medico-Chirurgical Society

This society held its 61st annual dinner on July 8 in the Drapers Hall. Alderman C. L. Ackroyd, proposing the first toast, said that Mr. B. Sangster Simmonds was not only president of the society but also master of the Drapers' Company, and had been elected to the latter office for a second year—almost a miracle in City circles. Mr. Sangster Simmonds pointed out that the society consisted mainly of practitioners and consultants in the West of London, and on this evening the matron and other members of the nursing staff of the West London Hospital were joining them. The years 1911 and 1948 had certainly not brought Utopia to general practitioners; indeed, the increasing demands of the population had almost overwhelmed them. But he hoped the time was not far off when practitioners would work as part of the organisation of a hospital, with the help of everyone else in that organisation. Mr. G. B. Woodd-Walker, proposing The Guests and Kindred Societies, managed to put all of them in a favourable light. Sir Ernest Pooley, responding, said that the medical profession has passed through difficult times, but he hoped that the working of the National Health Service Act will improve as years go by—given continuous effort by the profession. For the ordinary labouring man the provision of medical care was better than before—though there was still room for improvement. And it was a comfort not to have to pay for it directly. As "one of the oldest Drapers in existence," Sir Ernest recalled that the company had lived on the same site since the days of Henry VIII, and that its remaining garden contained a mulberry tree planted in James I's time and still bearing fruit. Dr. B. T. Parsons-Smith, president of the Hunterian Society, spoke of the features common to the West London and its fellow societies—all of them with their lectures, debates, and discussions (held without formality and with a minimum of ceremony), and their published transactions. Working independently of the National Health Service, these societies maintain, he said, the mastery of their traditions and their destinies.

Royal Institute of Philosophy

Six lectures are to be given at the institute, 14, Gordon Square, London, W.C.1, during the Michaelmas term on Fridays at 5.15 P.M., on Mind and its Place in Nature. Prof. J. Z. Young, F.R.S., is to give the first lecture on Oct. 17, and the other speakers will include Dr. C. G. Phillips and Dr. Macdonald Critchley.

Symposium on Brain Biochemistry

In a symposium on Brain B[illegible]s relation to Mental Disease, held at th[illegible] Bristol, on July 8 and 9, the following took part:

G. B. Ansell and D. Richter (Cardiff); S. P. Bessman, E. C. Layne, and S. Udenfriend (Washington); P. B. Bradley, J. Elkes, and J. B. Finean (Birmingham); J. J. Gordon and M. Reiss (Bristol); C. C. Kratzing, H. McIlwain, R. Rodnight (London); M. Schou (Denmark); H. Waelsch (New York).

Emergency Bed Service

The south western branch of the service at Wimbledon will be closed from 9 P.M. on July 20. The work of this office is being reallocated to the head office at Old Jewry, and the other three branch offices as follows:

The Boroughs of Wandsworth and Battersea will be covered by the head office at Old Jewry (Monarch 3000).

The county borough of Croydon will be covered by the south-eastern branch office at Woolwich (Woolwich 3471).

The remainder of the area will be covered by the western office at Ealing (Ealing 6671).

Recovering Silver from X-ray Films

The means by which something like 500,000 oz. of silver, worth over £150,000, can be recovered from used X-ray film each year, have been indicated to hospital authorities in England and Wales by the Ministry of Health. The silver recovered in this way will be returned to the X-ray film manufacturers to help overcome the shortage of this metal—a dollar import—which is essential in the making of X-ray films.

London County Council

Dr. A. B. Stewart, who is at present a divisional medical officer of health, has been promoted to the post of deputy medical officer of health.

Dr. Stewart, who is 44 years of age, graduated M.B. at the University of St. Andrews in 1931. After holding house-appointments at the Dundee Royal Infirmary he became lecturer and assistant in bacteriology in the medical school. In 1934 he took the D.P.H., and two years later he obtained his M.D. with commendation and was awarded the Rutherford silver medal for his thesis. He held the post of assistant M.O.H. at Tynemouth before he was appointed M.O.H. for Finsbury, and he is now acting M.O.H. for Paddington. His earlier published papers dealt with the identification and activity of streptococci. His later papers have discussed problems of public-health administration such as health centres and local-authority health services.

Prescriptions for Cod-liver Oil and for Glucose

In a circular to executive councils (E.C.L. 51/52) the Ministry of Health says that a number of [illegible] told by executive councils that [illegible] cases where cod-liver oil and malt extract has been prescribed. The Ministry recalls that in its first report (H.M. Stationery Office, 1950) the Joint Subcommittee on the Definition of Drugs recommended that, as a general principle, preparations intended primarily to provide nourishment in established disease should be classed as drugs; and it suggested that cod-liver oil, cod-liver oil and malt, and other vitamin preparations might be regarded as drugs when used, for example, in the treatment of tuberculosis or vitamin deficiency. The circular says that there also seems to have been some confusion over surcharging prescriptions for glucose. The joint subcommittee suggested that glucose, though primarily a food, might be a drug when given, for example, by intravenous injection or as compressed tablets for use by diabetics.

Dr. E. R. A. Merewether, senior medical inspector of factories in the Ministry of Labour, has been appointed medical advisor to the Ministry of Agriculture on medical questions arising out of the use of poisonous substances in agriculture.

The first number of the medical section of the *Bulletin Scientifique Roumain* was published in Paris this year. The bulletin is the organ of the former Rumanian Royal University Foundation of King Carol which has now been reconstituted in Paris. The following are members of the editorial committee: Dr. P. Atanasiu, Dr. J. [illegible]ovici, Prof. C. Levaditi, Prof. N. Metta, [illegible], Prof. P. Sergescu, Dr. T. Stoicoiu. The [illegible] Atanasiu, 6 rue de Val-de-Grâce, Paris, V, [illegible] Broussais, 96 rue Didot, Paris XIV.

AN OUTBREAK OF FEBRILE ILLNESS ASSOCIATED WITH A COXSACKIE VIRUS

H. KENYON
M.B. Birm.
GENERAL PRACTITIONER

A. D. MACRAE
M.D. Aberd., Dip. Bact.
ASSISTANT BACTERIOLOGIST, VIRUS REFERENCE LABORATORY, COLINDALE

R. J. DODDS
M.B. Durh., D.P.H.
DEPUTY MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER, COVENTRY

J. F. GALPINE
M.D. Leeds, M.R.C.P.E., D.P.H.
MEDICAL SUPERINTENDENT, WHITLEY HOSPITAL, COVENTRY

ISOLATION of a Coxsackie virus from the fæces of children with paralysis was first reported by Dalldorf and his co-workers (1948, 1949), and Curnen et al. (1949) isolated a Coxsackie virus from patients with a disease resembling non-paralytic poliomyelitis. Other reports associated these viruses with epidemic pleurodynia and Bornholm disease (Weller et al. 1950, Findlay and Howard 1950) and with a mild febrile illness of three to five days' duration, mainly among children (Huebner et al. 1950, Howitt 1950). Since then strains of Coxsackie virus have been isolated from patients with herpangina, a condition characterised by fever, sore throat, and a vesicular or ulcerative pharyngitis (Huebner et al. 1951, Parrott et al. 1951).

On the basis of the lesions in newborn mice, two groups of virus have been described: group A causes diffuse myositis only, and group B causes cerebral and visceral lesions, with changes in the fat pads and less obvious myositis. In addition immunologically distinct strains of virus occur within the groups.

In human serum both neutralising and complement-fixing antibodies develop in response to invasion by these viruses, and it is thus likely that they can cause illness in man.

We describe here an outbreak, in a semi-closed community, of an illness associated with a group-B strain of Coxsackie virus.

Epidemiological Background

In May, 1951, illness broke out in a residential children's home, established in a mansion in the country a few miles from the outskirts of Coventry, where the children attend either an ordinary school or a nursery school, according to age. All the children in the home and most of the resident staff receive medical attention from one of us (H. K.), who is also the family doctor for many of the local children going to the same schools. No illness appearing clinically identical with that in the children's home was noted in these other children or their families, although, during the same period as the outbreak in the children's home, two types of brief febrile illness, lasting less than a week, were encountered in the district, the one undistinguished by any particular clinical feature and the other accompanied by transient neck rigidity. The illness in more than half the cases in the children's home lasted longer than a week and no neck rigidity was found. At this time another of us (J. F. G.) noted, in another part of the Coventry area, a family outbreak of a similar febrile illness, involving three children: a girl aged 3 years, and boys aged 8 and 10. The girl and the younger boy had febrile illnesses with a maximum temperature of 103°F and lasting for about two days; the elder boy had a febrile illness with a maximum temperature of 105°F, malaise, and headache, and lasting for about ten days.

The children in the residential home, in number just over 60, vary in age from 3 years to 15 and are in three groups—namely, "infants" aged 3–6 years, and separate groups of boys and girls aged 7–15. Each group has separate accommodation for sleeping and dining. Of the staff 11 are resident and 12 non-resident. On May 15, 1951, the foster-mother of the infants and one of her charges, a boy aged 6, sickened. From then until June 1, the main period of the outbreak, no day passed without at least one new case, the greatest number of new cases on any one day being 6. During the first eight days of this period (up to and including May 22) cases arose exclusively in the infant group or in adults associated with that group; on May 23 and thereafter the older children were involved (see figure).

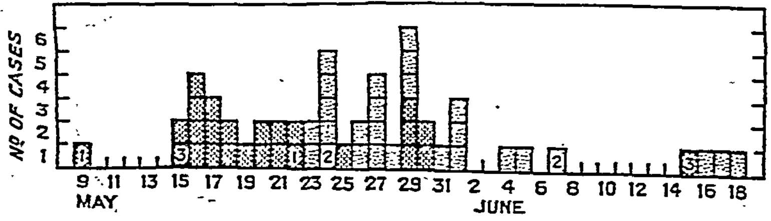
It may be noted that a child aged 4 had become feverish and vomited on May 9; she recovered quickly, however, and no particular significance was attached to this at the time. The child again sickened on May 22, and it is interesting to conjecture whether this second illness was her first attack of the epidemic disease or a relapse. If it was a relapse her illness of May 9 and 10 was the first case in the outbreak, preceding all the others by six days.

TABLE I—AGE AND SEX INCIDENCE

Age-group (yr.)	No. of males in group	No. of males affected	No. of females in group	No. of females affected
3–6	12	12	11	9
7–15	18	9 (1)	22	14
Resident adult staff..	3	0 (1)	9	6
Total	33	21 (2)	42	29

The numerals in parentheses represent cases not mentioned in the clinical notes or in the figure, because detailed records were unavailable.

Two patients who fell sick in the main period of the outbreak relapsed 31 and 14 days after the initial onset (see figure), and other patients had short intermissions of symptoms and signs lasting a day or two. In all, 52 out of 75 residents in the home and possibly 3 of the non-resident staff were affected. The following notes are based on a study of 50 of these cases (including 44 children) for whom detailed records are available.



Time-incidence of cases: *hatched*, Infants aged 3–6 years and 3 adults associated with them; *stippled*, children aged 7–15 years and 2 adults associated with them and 1 kitchen worker. Paired numerals relate to relapses.

Clinical Features

The illness showed a fairly uniform pattern with pyrexia, headache, nuchal pain, repeated vomiting, and vague abdominal pain as the commoner features. The rapid spread involved many children at the same time, and the bedrooms in the home were quickly filled with sick children, who, however, recovered as soon as their temperatures finally settled. No difference in sex-incidence was apparent, but the "infants" appeared to be somewhat more susceptible than the older children and adults, although a high degree of susceptibility was general (table I).

Pyrexia

Pyrexia was present in all cases and started abruptly with a rapid rise of temperature to 101°–102°F with a maximum of about 104°F. There was great variation in the duration of the pyrexia, which could be as brief as two or three days or as long as six weeks. Thus, whereas in 18 cases the temperature settled within seven days, in 12 cases it finally settled between seven and fourteen days and in the remaining 20 cases lasted for more than fourteen days. In the 12 cases of medium duration the temperature after the first days of illness either fell to a lower level, at which it remained until finally settling (5 cases), or else, after a return to normal for about forty-eight hours, recrudesced before final resolution (7 cases). In the longer cases an irregular pyrexia with several sharp peaks was the general finding.

Toxæmia

No patient was so ill as to cause serious anxiety, but in the early stages prostration was noticeable, especially where vomiting was pronounced; after lasting for a few hours or a day it often ended suddenly.

Headache and Nuchal Pain

A *frontal headache*, often unilateral, occurred in all cases, lasted one to three days, and was always a presenting symptom. It was complained of at onset and recurred (as a rule less severely) with any recrudescence of pyrexia.

A fairly severe *nuchal ache* was noted in 34 cases; this too was an early symptom. It did not usually return with a recrudescence. Neck rigidity was carefully sought by three of us but never found. In 2 cases in which lumbar puncture was done the cerebrospinal fluid (C.S.F.) was normal.

Backache was complained of in only 1 case, and limb pains were not of a severity to be especially noted.

Nausea and Vomiting, Diarrhœa, Abdominal Pain

Repeated vomiting, during the first one to three days occurred in 34 cases and was troublesome; in 2 others there was nausea alone. The number of vomits varied from 1 to 8 in twenty-four hours, usually recurring with a recrudescence or relapse.

Diarrhœa occurred in 8 cases—all towards the end of the outbreak. The stools did not contain macroscopic blood or mucus. In 7 of these cases there was vomiting also.

Abdominal pain occurred in 41 cases but was vague, diffuse, and never sharp or severe or a cause of anxiety.

Chest Pain

Pain in the chest was described in 18 cases either at onset or with a recrudescence. It lasted for a day or two and took the form of a "tight" aching sensation in the sternal area. Cough was not complained of, nor were physical signs found in the chest. Of the more prolonged cases, 7 had chest radiographs in the later stages, but the only notable finding was a temporary enlargement of hilar glands in one child. This child and one other had a suggestion of diffuse and light inflammatory change in the right lower zone; both these children had had pain in the chest.

Herpes Simplex

Herpes occurred in 24 cases in the common circumoral position, and ulcerative stomatitis in 2 others. The most pronounced herpes was seen in a case in the short-duration group, which, however, had the smallest proportion—3 herpes in 18 cases, compared with 11 of 12 in the medium-duration group and 12 of 20 in the longer-duration group. Age did not seem to influence the incidence of herpes.

Sore Throat

Definite sore throat occurred in 6 cases; 4 of these had soft white tonsillar exudate, and 3 of them were swabbed for culture. A few other patients had congested fauces—in 1 case unilateral.

Other Symptoms

In 2 cases there was an urticarial rash. A girl, aged 18, who was ill for thirty-nine days, had temporary mistiness of vision, and a woman, aged 42, with a twelve-day attack, complained of fainting and vertigo.

Treatment

At the beginning of the outbreak patients were placed on a five-day course of sulphamerazine, but this was soon abandoned because it seemed to exert no influence, and treatment thereafter was symptomatic only. It was decided to try aureomycin in 2 prolonged cases, but the temperatures became normal just before the drug could be given and so may have saved a *post hoc propter hoc* dilemma.

Case-records

The following are summaries of 5 cases which provided specimens for virus investigations.

Case 1.—An epileptic girl, aged 15, had pyrexia reaching 102°F, headache, nuchal ache, pain in the chest, and abdominal pain, but no vomiting. On the fourth day her pyrexia subsided, but ten days later it recurred, reaching 101·8°F, and remained at a lower level until it finally subsided in the third week of the second attack.

Case 2.—A girl, aged 7, had a temperature reaching 102°F which became normal on the third day. She complained of headache, nuchal ache, and chest pains; she did not vomit or have abdominal pain. She had herpes simplex and injected fauces.

Case 3.—A boy, aged 9, had a normal temperature on the third day, but had further small rises between the fourth and seventh days, followed by two pronounced spikes (from normal level up to about 103°F) on the eleventh and fifteenth days. His pyrexia finally settled on the nineteenth day. He complained of headache and severe nuchal pain and vomited, and he had herpes simplex. His C.S.F. gave normal findings: cells less than 1 per c.mm.; chlorides 760 mg., protein 40 mg., and sugar 54 mg. per 100 ml.

Case 4.—A boy, aged 5, had pyrexia which finally settled about the sixth day. He complained of headache, nuchal pain, and abdominal pain. He also vomited repeatedly and copiously during his first two days' illness. His C.S.F. was normal: leucocytes less than 1 per c.mm.; chlorides 780 mg., proteins 30 mg., and sugar 72 mg. per 100 ml.

Case 5.—A boy, aged 8, had pyrexia reaching 101°F which did not finally settle until the eighth day, though the temperature had been normal on the fourth and sixth days. He complained of headache and abdominal pain and vomited.

Laboratory Investigations

Specimens of fæces from cases 1–5 were negative when cultured for the salmonella and dysentery groups of organisms.

In 2 cases (case 4 and another) agglutination tests were negative for the enteric group and non-specific for salmonella and *Brucella abortus*.

In 3 cases with prolonged pyrexia—2 girls (A.B. and C.D., aged 8 and 13 respectively) and a boy (E.F., aged 9)—the cold agglutinin reactions and Paul-Bunnell tests were negative. A.B. and E.F. had white-cell counts of 8000 and 7000 per c.mm. respectively, with normal differential counts, but C.D. had a white-cell count of 9500 per c.mm. (polymorphs 31%, lymphocytes 65%, large mononuclears 4%).

Chest radiographs were taken of A.B. and C.D. in a search for the cause of the continued pyrexia. C.D. had some enlargement of the hilar glands visible on the lateral film, and in the lung fields of both A.B. and C.D. there were slight basal changes. The hilar enlargement and the basal changes had disappeared when radio-

ABLE II—SPECIMENS USED FOR VIRUS INVESTIGATIONS

e	Specimens A, B, C	Duration of illness (days)		
		A	B	C
	Throat washings and fæces A; serum A, B, C	1	22	192
	Throat washings and fæces A; serum A, B, C	1	22	192

	Throat washings A; serum A, C	3	—	203
	Throat washings A; serum A	5	—	—

aphy was repeated a fortnight later. Both A.B. d C.D. were Mantoux-negative 1/1000. Five other ildren with prolonged pyrexia had normal chest diographs.

In 3 cases with tonsillar exudate faucial cultures were egative for β-hæmolytic streptococci and *Coryne-* *cterium diphtheriæ*. Stained smears showed no Vincent's ganisms.

VIRUS INVESTIGATIONS

From the specimens shown in table II virus-isolation nd serological investigations were undertaken.

Iethods used in Virus Isolation

From the original specimens pools of material were repared as follows:

Pool 1 consisted of equal volumes of throat washings from ases 1, 2, and 5.

Pool 2 consisted of equal volumes of throat washings from ases 3 and 4. Each pool contained 1000 units of penicillin nd streptomycin per ml. The separate throat washings were subsequently investigated also.

Pool 3.—A 20% suspension in saline solution was prepared rom each specimen of fæces. After standing overnight in the efrigerator the suspensions were centrifuged on a horizontal entrifuge at 5000 r.p.m. for one hour. The supernatant fluids were retained, deposits being discarded. Portions of each suspension containing 200 units penicillin and 2000 units of streptomycin per ml. were set aside. Equal volumes of these were mixed to form a pool. The separate suspensions and the pool were left for one hour at room-temperature and next stored in the refrigerator until aerobic and anaerobic cultures were made on blood-agar plates.

Inoculation of Mice

Litters of newborn mice were inoculated when available. Single litters averaging 5–9 mice were used unless 3 or more litters born on the same day were available, when these were pooled and distributed evenly. A standard inoculum of 0·02 ml. of suspension was injected subcutaneously over the scapular region of mice aged twenty-four to forty-eight hours. Deaths occurring within forty-eight hours after inoculation were regarded as non-specific. From forty-eight hours to twelve to fourteen days, deaths involving most of the inoculated animals were accepted as specific if preceded by retardation of growth, weakness, ataxia, coarse tremors, and paralysis. For passage, mice were killed with ether when they showed signs of illness. They were decapitated, skinned, and eviscerated, and 20% suspensions in saline solution were prepared. After overnight storage in the refrigerator these were centrifuged at 3000 r.p.m. for thirty minutes, and the supernatant fluids were used. Titrations were made with tenfold dilutions in saline solution.

Neutralisation Tests

These were made with the available specimens of serum and the newly isolated strains of Coxsackie virus. After inactivation at 56°–58°C for thirty minutes ndiluted or diluted sera were mixed with equal volumes of saline suspensions containing about 100 LD$_{50}$ of virus. The mixtures were shaken and left at room-temperature for one hour before inoculation into mice.

Preparation of Immune Mouse Serum

Adult mice were given six intraperitoneal injections of 0·2 ml. of a 33% suspension of pool-3 infected newborn mouse tissue within a period of three weeks. They were bled out ten days after the last inoculation. Repeated intraperitoneal inoculation of adult mice and guineapigs with concentrated virus suspension did not cause illness in either species of animal.

Isolation of Coxsackie Virus

Strains of Coxsackie virus were isolated from pools 1, 2, and 3, from all the individual throat washings, and from individual fæcal suspensions from cases 1 and 2, but not from case 5. Signs of illness were noted five to eleven days after inoculation and progressed to complete paralysis and death usually within two or three days. Despite the development of weakness and tremors, recovery sometimes took place, especially during initial passages. Repeated passage brought the incubation period to five or six days after inoculation, and titres of about 10^{-6} dilution of suspension were usually obtained. No lesions were caused by this virus on the chorio-allantoic membranes of fertile eggs. This fact, together with the isolation of virus from fæces, excluded the possibility of its being a strain of herpes-simplex virus.

Histological examination of mice infected with the strain of virus isolated from pool 3 was undertaken by Dr. A. Beck, of the North West Group Laboratory, London, who reported as follows:

Heart.—Small areas of necrosis and disintegration of muscle-fibres and infiltration of the ventricular wall with polymorphs and histiocytes.

Fat pads.—Small areas of degeneration and necrosis in the lobules of embryonal fat and infiltration with polymorphs and histiocytes.

Brain.—A few small foci of lymphocytic infiltration in the grey matter.

Influenza Virus

An unsuccessful attempt was made by Dr. B. P. Marmion to isolate influenza virus from the pools of throat washings.

Herpes-simplex Virus

No attempts were made to isolate this virus from the circumoral vesicles which appeared in many of the affected children.

SEROLOGICAL INVESTIGATIONS

Complement-fixation Tests

The A and B specimens of serum from the 5 patients were negative when tested against influenza A and B, psittacosis group, and *Rickettsia burneti* antigens. The *Streptococcus M.G.* agglutinations were also negative.

TABLE III—RESULTS OF NEUTRALISATION TESTS WITH POOL-3 VIRUS SUSPENSION AND HUMAN SERA

Case no.	Serum	Serum dilution				Saline control
		1/1	1/5	1/10	1/50	
1	A (1)†	..	4/4*	..	..	3/3*
,,	B (22)	..	0/4	..	2/4	3/3
,,	C (192)	..	2/5	..	..	4/4
2	A (1)	4/4	4/4	..	..	4/4
,,	B (22)	..	..	2/4	4/4	3/3
,,	C (206)	0/6	..	..	..	4/4
3	A (3)	8/8	..	..	..	3/3
,,	C (203)	1/5	..	..	..	2/2
4	A (5)	2/3	..	..	..	3/3
5	C (192)	2/4	..	..	..	4/4

* This indicates the number of mice which died as a result of the inoculation over the number of mice inoculated. Surviving mice were those alive at the time of weaning, when they were four weeks old. Deaths from specific infection took place up to fourteen days after inoculation, and mice which survived until then rarely succumbed afterwards.

† The figures in parentheses represent the day of illness on which the serum was obtained.

The A specimens of serum from cases 3 and 4 and the B specimens from cases 1 and 2 were negative when tested against Dalldorf's types I and II and Melnick's High Point strains of Coxsackie virus antigens.

Neutralisation Tests

The A and B specimens of serum from case 5 had all been used; so neutralisation tests could not be attempted. Only small volumes of some of the other samples were available, and the tests had to be made with these, starting with the lowest dilution of serum possible. The results are given in table III.

Only limited conclusions may be drawn from these tests, because only a few mice were used and only small amounts of some of the sera were available. It does appear, however, that the strain of virus used was not neutralised by sera obtained before the fifth day of illness, and that some neutralising antibody was present on the fifth day of illness, being still there about six or seven months after the infection.

It was necessary to decide whether the strains of virus isolated from the different suspensions were identical. A neutralisation test was first made with the newly prepared immune mouse serum and the homologous virus suspension as follows:

Virus	Immune mouse serum dilutions			Control saline
	1/5	1/50	1/500	
Pool-3 suspension	0/4*	2/5	2/5	1/3

* See table III.

Although only 1 of the 3 control mice died, the control mice and those inoculated with the 1/500 dilution of serum developed weakness and coarse tremors of the head and limbs after inoculation, whereas those given the 1/5 and 1/50 dilutions of serum did not. It was therefore decided to use a 1/50 or lower dilution of serum in the subsequent tests. The results are given in table IV.

The results indicate that all the strains of virus were neutralised by the immune mouse serum and were antigenically related if not identical.

As histological examination of infected mice had shown that the newly isolated virus belong to the Coxsackie-B group of viruses, an investigation to see whether there was an antigenic relationship to the Connecticut-5 strain of virus was carried out. In this a strain of Connecticut-5 virus received from Dr. Melnick and some group-B1 mouse antiserum from Dr. Dalldorf were used. The results are given in table V. No antigenic relationship between the newly isolated virus and the Connecticut-5 strain of Coxsackie virus is apparent.

Discussion

The epidemic was a troublesome episode. The work of the residential home was temporarily dislocated, and the difficulties of nursing so many children at once were great, especially as some of the staff were also ill. Certainly none of the children were dangerously ill, but many o them were quite poorly in the early stages, and ofte the illness was rather prolonged.

Of the 75 residents in the children's home 52 becam ill, and 45 of these cases arose during a period of eightee days. The condition was thus highly infectious withi the semi-closed community of the children's home that there was also a general susceptibility was mos obvious in the infants (21 cases out of 23) but als evident in the adults, 6 of 9 female staff being affecte (*table* I).

Although there was great variability in duration of the illness from several days up to about a month, there was a uniformity of clinical picture easiest to appreciate in the early stages. The longer cases showed remissions or intermissions. In 3 cases there were intermissions, of thirteen, fourteen, and thirty-one days, and they are indicated in the accompanying figure as relapses. In view of the long period of intermission in these cases the recurrence of illness possibly followed infection by a different strain of virus. This point was not investigated.

The commonest features were headache, nausea and vomiting, vague abdominal pain, and a nuchal ache without rigidity. Less constantly there was an aching pain in the sternal area. Backache was not a feature. A few patients had sore throats, and a few diarrhœa. Toxæmia was never severe, but some patients were somewhat prostrated at the onset.

The influenza epidemic of 1951 died out in this area about the end of February, and the comparatively long course of many of the present cases and the general lack of respiratory symptoms were inconsistent with a diagnosis of influenza. The absence of any sharp pain in chest or abdomen was against Bornholm disease. The lack of meningeal signs or paralysis virtually excluded poliomyelitis, and the C.S.F. was normal in 2 cases tested; though cases of a non-paralytic syndrome were at this time appearing with increasing frequency in Coventry. 7 patients had their chest radiographed, and the slender findings in 2 of these, though insufficient for forming any conclusions, generated a suspicion that radiography at an earlier stage might have revealed something more definite. In 3 cases Paul-Bunnell and cold-agglutinin tests were made; they gave negative results. None of the clinical features were characteristic of enteric fever, and fæcal specimens from 5 patients were negative for salmonella organisms. Sera from the same patients were negative for the psittacosis group, *R. burneti*, *Strep. M.G.*, and influenza A and B.

Finally, from the same 5 cases throat-washings and fæces were examined for Coxsackie virus because of the unusual clinical characteristics of the outbreak, and an apparently identical strain of group-B Coxsackie virus was recovered. Neutralising antibody was not found in serum taken in the first three days of illness but was found in serum taken on the fifth day or later. The evidence suggests that this strain of Coxsackie virus was the cause of the outbreak.

The immediate origin of this strain is conjectural. It has been stated that, in the area served by the school used by the residential home, there was some minor

TABLE IV—RESULTS OF NEUTRALISATION TESTS WITH 1/50 DILUTION OF IMMUNE MOUSE SERUM

Virus suspension	Serum and virus	Control saline and virus
Pool 1, 4th-passage suspension	1/7*	1/1†
Pool 2, 2nd-passage suspension..	0/6	1/1†
Case 1, 1st-passage stool suspension	0/5	3/3
Case 2, 3rd-passage stool suspension	1/5	2/2
Case 5, 2nd-passage throat washings suspension	1/6	4/4

* See table III.

† Although only one control mouse has been included in these tests it was known from previous results that the dilution of suspension used would invariably cause the death of inoculated mice.

TABLE V—RESULTS OF NEUTRALISATION TESTS

	Coxsackie-B1 mouse antiserum		
Pool-3 suspension	4/4		3/3

* See table III.

febrile illness whose constant brevity and very mild nature did not suggest identity with the illness at the children's home. It is, however, easiest to believe that the virus was of local origin and imported into the children's home through school or other contact, especially as present knowledge suggests that man is the main reservoir and conveyor of Coxsackie virus. Further, a pathogenic virus present in throat washings and probably capable of droplet spread would have optimum conditions for direct aerial transmission within a susceptible population living under one roof. The rapid involvement of the infant group, followed by the equally rapid spread through the associated but separate groups of older children, seemed consistent with this mode of spread, as also did the infection of 2 adult staff who were friendly and who fell sick consecutively, with illnesses separated by a few days. Indirect transmission through food and drink or other contaminated articles was another possibility, which may have become more likely as fæcal convalescent carriers accumulated. Infection from an animal reservoir, such as rodent pests might provide, appears to be on the whole unsupported by present knowledge of Coxsackie epidemiology. Much the same problems regarding mode of spread arise in poliomyelitis as arose in this outbreak of febrile illness.

If the spread was direct from case to case, the incubation period was about a week. This view is based on the period between the start of the main outbreak in the "infants" and that in the older children (eight days); the period between the first two peak days on May 16 and May 24 (also eight days); the interval between the illnesses of the 2 adult friends mentioned earlier (six days); and between the illness of the child on May 9 and the first cases of the main batch on May 15 (six days), if the sick child on May 9 (whose illness achieved importance mainly in view of subsequent events) can be accepted as the actual first case—a point on which we are not unanimous.

In conclusion it may be said that the problem of "pyrexia of unknown origin" is one which, even in these days of rapidly expanding knowledge and wide range of laboratory tests, still baffles. Experience in this outbreak, however, suggests that the problem may be further reduced when facilities for Coxsackie virus investigations become increasingly available.

Summary

An outbreak of febrile illness involving 52 out of 75 persons in a residential children's home is described.

A group-B strain of Coxsackie virus was isolated from mouth washings and fæcal specimens from patients; neutralising antibody was absent in early sera but appeared in sera from the fifth day onwards.

The differential diagnosis and the possible immediate origin of the outbreak are discussed briefly.

Our thanks are due to Dr. R. Ewart Jones for bacteriological and other assistance; to Dr. A. Beck for the pathological report; to Dr. B. P. Marmion; to Dr. J. L. Melnick for the strain of Connecticut-5 virus; and to Dr. G. Dalldorf for the group-B antiserum. We are also much indebted to Mr. and Mrs. D. Parsley, then superintendent and matron of the residential children's home, for their coöperation and help.

INTRA-ARTERIAL TRANSFUSION

D. L. C. BINGHAM
M.B. Edin., F.R.C.S.E., F.R.C.S.(C), F.A.C.S.
PROFESSOR OF SURGERY IN THE QUEEN'S UNIVERSITY,
KINGSTON, ONTARIO, CANADA

TRAUMATIC shock, a clinical syndrome in which the outstanding feature is acute collapse of the peripheral circulation, is an ever-present emergency both in peace and war. It requires immediate and effective treatment, if life and limb are to be saved, and deliberate curative surgery made possible.

SHOCK

Fundamentally, shock may be defined as that state which results when disparity arises between the volume of the vascular bed and the circulating blood volume. This may occur:

(1) When the circulating blood volume is rapidly reduced by hæmorrhage, loss of plasma, or excessive loss of body-fluids. (Any combination of these three causes of blood-volume depletion may occur.)

(2) When the volume of the vascular bed is rapidly increased without comparable increase in circulating blood volume. This may take place with great rapidity as the result of widespread and rapid decrease in tone of small arteries, veins, and capillaries, either reflexly or from some other cause.

In both main groups of causes the all-important sequel is inadequate filling of the vascular bed. As a result blood-pressure rapidly falls until an unstable equilibrium between blood volume, vascular-bed volume, and the now reduced blood-pressure is established. Later, owing to the urgent necessity for maintaining the rate of blood-flow through vital organs—e.g., brain, heart, liver, and kidneys—the circulating blood volume is increased by extraction of fluid from the tissue spaces, and the vascular-bed volume is reduced by an increase of tone in small blood-vessels and widespread contraction of capillaries. Equality or near equality may thus be re-established between blood volume and vascular-bed volume, and blood-pressure will accordingly rise, perhaps even to normal, and shock may apparently be overcome. This apparent recovery from shock is dangerously misleading and is often spoken of as the compensatory phase of shock, or "masked shock," and a patient who is operated on while in this phase, without preliminary blood-transfusion to restore his blood volume to its former level, is in great danger of developing an overwhelming degree of shock from the additional trauma of the operation.

Another and highly lethal set of circumstances may arise in the patient who has lost a substantial fraction of his blood volume but has, for the time being, wholly or partly overcome the initial depression of blood-pressure by compensatory mechanisms. Much of his apparent recovery is due to widespread constriction of small blood-vessels in relatively less important organs such as the skin and subcutaneous tissues. This state of enhanced vascular tone cannot be indefinitely sustained, because tissues deprived of their normal blood-supply are also deprived of their normal nutrition and means of getting rid of the waste products of their metabolism. Injurious metabolites consequently accumulate in such relatively ischæmic tissues until they reach a concentration at which they cause local vasodilatation, and probably also a generalised decrease in vascular tone. As a result the vascular-bed volume begins to enlarge, and an increasing degree of disparity between it and the circulating blood volume arises, with a resulting drop in blood-pressure and a decreased rate of blood-flow through all the body tissues. A vicious circle then develops which leads rapidly on to irreversibility, a state in which peripheral vascular failure is so profound that pooling and laking of the remaining circulating blood in the relaxed vascular bed take place, and transfusion, even in apparently adequate amounts, is then unable to prevent the death of the patient.

From this brief discussion, which could be elaborated almost indefinitely, one outstanding concept emerges—namely, that, to sustain the well-being and nutrition of each one of us, not only must the heart deliver at a normal pressure an adequate quantity of blood but also (so that normal blood-flow through all the tissues shall be maintained) the blood volume, the volume of the vascular bed, and blood-pressure (peripheral resistance) must be normal. Thus, assuming that the heart can work properly, circulatory efficiency depends on the presence of a normal blood volume, a normal vascular-bed volume, and normal tone or peripheral resistance in the vascular channels. Perhaps this concept can conveniently be expressed in the following equations:

(1) Circulatory efficiency = normal blood volume + normal vascular-bed volume + normal blood-pressure.

(2) Circulatory inefficiency or shock = reduced blood volume + abnormal vascular-bed volume + reduced blood-pressure.

These concepts (represented diagrammatically in fig. 1) will, I believe, be generally acceptable. Until recently, however, efforts to resuscitate patients in a state of shock or circulatory inefficiency have largely been directed towards restoring blood volume to normal by intravenous blood-transfusion.

This method has justly been acclaimed as an immensely valuable means of overcoming shock and has saved countless lives. But it depends for its success on a substantial and increasing degree of tone in the smaller peripheral vascular channels, so that blood added to the blood volume intravenously will be returned to the heart and thus to the general circulation. If a reasonable degree of vascular tone is not present—e.g., in late and severe shock—blood which is given intravenously will largely accumulate in venous channels and capillaries, and may indeed never pass through the heart and lungs to the arterial side of the circulation. Tissue anoxia and malnutrition thus persist, and the patient's condition becomes progressively more perilous.

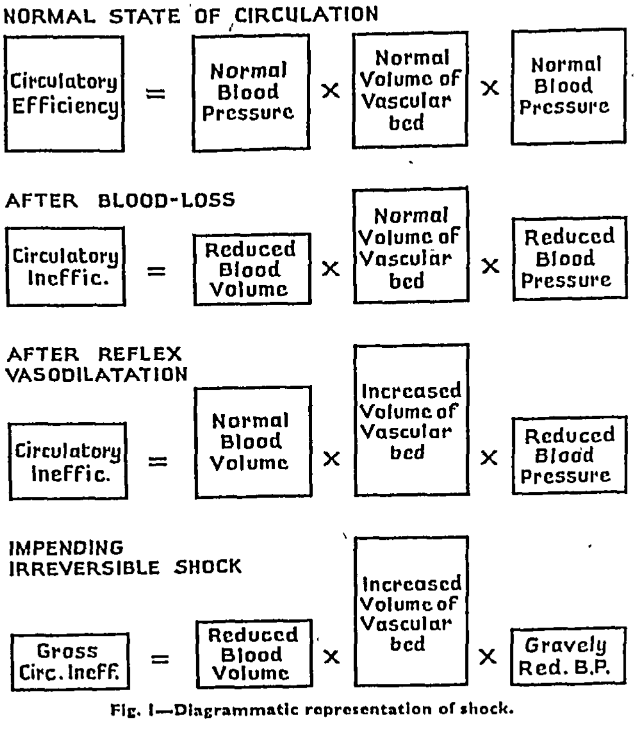

Fig. 1—Diagrammatic representation of shock.

Attempts to reduce the volume of the vascular bed with vasopressor drugs have been disappointing and even deleterious in severe shock. In the early phases they add to the already severe vasoconstriction and thus further deplete capillary blood-flow and increase tissue anoxia. In the later stages of shock their vasoconstrictor effort is fleeting, the anoxic, relaxed, and malnourished capillaries being incapable of sustained contraction even when adequate intravenous blood-volume replacement has provided at least one of the primary requisites for recovery.

A third alternative is, however, available—that of increasing blood-pressure rapidly to normal by intra-arterial transfusion at or above physiological pressures.

INTRA-ARTERIAL BLOOD-TRANSFUSION

The introduction of blood into the arterial tree under pressure at about 120 mm. Hg, or slightly above this figure, causes the blood-pressure within the whole arterial system to rise rapidly to normal (Robertson et al. 1948). Intra-arteriolar and intracapillary pressure is restored, and perhaps pooled and laked blood, lurking in flaccid capillaries and venules, is pushed onwards into the great veins and so back to the heart, which is thus once again provided with blood to pump onwards.

A dangerous state of circulatory collapse may thus be reversed almost immediately. Indeed, circulatory puissance replaces circulatory prostration, and the nutrition of the whole body is improved. Almost inevitable death may thus be avoided and probable recovery substituted.

In broad outline the valuable results of intra-arterial transfusion in shock are:

(1) Normal systolic blood-pressure is restored throughout the whole arterial system almost at once.

(2) The rate of blood-flow through all body tissues—notably the brain, the coronary vessels, the liver, and the kidneys—rises rapidly.

(3) Adequate tissue oxidation replaces gross and increasing tissue anoxia.

(4) Accumulating tissue metabolites are washed away to their sites of detoxication or excretion.

(5) Lost blood is replaced as easily and quickly as by the intravenous route.

It is curious that intra-arterial transfusion has not yet been universally adopted for the treatment and prevention of shock. Indeed it does not seem to have been seriously used at all until 1939 when Birillo employed it with success. Kohlstaedt and Page, acting on a suggestion of Colonel Sam F. Seeley, Medical Corps, U.S. Army, first used the method in the United States in 1943. Since that time Glasser and Page (1946), Shaffer (1947), Kay and Hacker (1947), and Robertson et al. (1948) have reported on it. It was this last report that enlisted my own interest, and since 1949, at the Queen's University, we have investigated its possibilities both clinically and experimentally. The experimental studies are being reported elsewhere by L. S. deS. Carey and his associates. In summary, these workers have found that intra-arterial transfusion is much more effective than intravenous transfusion in the treatment of hæmorrhagic shock, and that its advantages include immediate restoration of coronary, cerebral, and renal circulation to normal and rapid return of blood-pressure to normal (Carey and Harrison).

Clinically we now use intra-arterial transfusion both in the treatment of established shock and as a prophylactic measure in all major surgical operations—e.g., pneumonectomy, thoracolumbar sympathectomy, and major abdominal operations—which may be complicated by severe shock.

METHOD

The apparatus is simple (fig. 2). An ordinary Baxter transfusion bottle containing 500 ml. of blood is used.

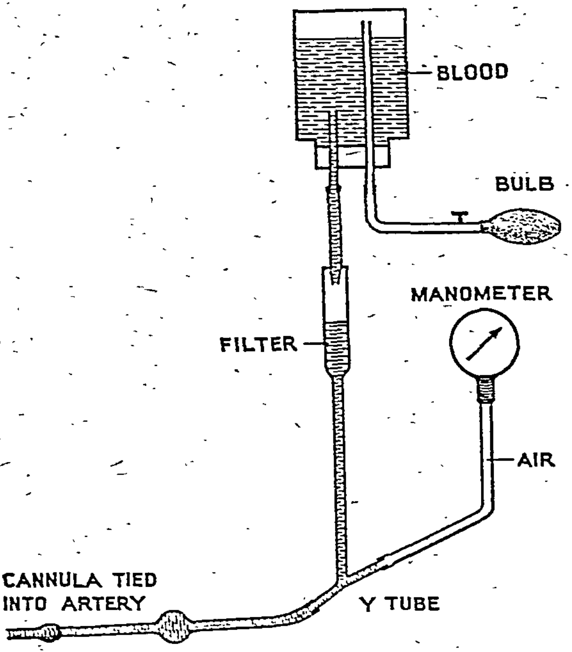

Fig. 2—Apparatus for intra-arterial blood-transfusion.

Heparin (1000 units) is added to the blood as an additional safeguard against clotting. To the longer glass tube, which reaches nearly to the bottom of the bottle, is attached a sphygmomanometer bulb by which controlled air-pressure can be applied to any desired level above the blood in the reservoir. To the shorter glass tube is attached the usual sterile rubber or latex tubing containing a filter. Beyond the blood filter there is a sterile glass Y-tube, from one arm of which is led a sterile rubber tube containing air. This tube is connected to an ordinary aneroid gauge attached to a stand slightly above heart level. The final rubber tube for the administration of blood to the patient is then attached to a cannula inserted into either the radial or the dorsalis pedis artery. This apparatus is the simplest and most foolproof that we have been able to devise with materials available in almost any hospital. Pressure within the system is continuously recorded by the manometer, which depicts the pressure at which blood is being delivered into the arterial system. It also is a valuable means of estimating intra-arterial pressure.

The following are among the minor difficulties we have encountered. Connections between tubing and cannula, bottle, blood filter, and aneroid manometer must be secure, or leakage may occur. The cannula must be directed towards the heart and must be tied into the artery, or leakage round it may take place. It is desirable to support the arm with a lightly applied crêpe bandage to present suffusion of the limb. In two cases ischæmia of the radial half of the hand developed: in one case this was immediately overcome by injection of the stellate ganglion with 0·5% procaine, and in the second case the terminal phalanx of the index finger was lost. Apart from these difficulties we have encountered no important complications. On the contrary, we have experienced nothing but satisfaction from intra-arterial transfusion. It has saved at least six lives and greatly facilitated and accelerated the recovery of many other patients.

One other possible danger exists—air embolism. We have not yet encountered this complication, because all the intra-arterial transfusions are continuously supervised. In addition a check valve is being incorporated into the apparatus to prevent its occurrence.

Intra-arterial transfusion has recently been used in the treatment of the phase of hypotension which succeeds coronary infarction from coronary thrombosis. Frequently these patients are admitted to hospital moribund with a systolic blood-pressure of 60 mm. Hg or less. Although it may seem unwise to add blood to the circulation, the immediate increase in intra-arterial pressure which results from intra-arterial transfusion may reverse the state of shock and save the patient. My colleague, Prof. Malcolm Brown, has lately had experience of such a case, and when more experience has accumulated he will no doubt be reporting his impressions.

ILLUSTRATIVE CASES

Case 1.—Mr. A had carcinoma of the left lung, and was undergoing pneumonectomy. Five minutes after the left pulmonary artery was ligated the atheromatous vessel ruptured at the proximal ligature. There was an immediate and profound fall of blood-pressure, with considerable loss of blood. Fortunately an intra-arterial transfusion was running. The bleeding pulmonary artery was secured, and within fifteen minutes of accelerating the rate and increasing the pressure of the intra-arterial transfusion the patient's systolic blood-pressure returned to its former level of 120 mm. Hg. He left hospital fifteen days later.

Case 2.—Mrs. B, aged 72, had carcinoma of the rectum, and was undergoing abdomino-perineal resection. All went normally until the rectum was removed; but then numerous small veins on the side walls of the pelvis and on the posterior aspect of the vagina bled profusely and were very difficult to control either by ligature or by pressure. In spite of intravenous transfusion, which kept pace with the rate of blood-loss, the systolic blood-pressure fell to 65 mm. Hg. An intra-arterial transfusion was then started, and within ten minutes her blood-pressure had risen again to 130 mm. Hg, after which her progress was uneventful.

In these and many other operations, which would either not have been attempted or have occasioned great anxiety after operation, the patients have either been saved or their immediate postoperative period has been much simplified. I can think of no measure more reassuring to the surgeon, and more capable of averting catastrophe, and I only wish that I had had it at my command during my service with field surgical units in the late war.

CONCLUSIONS AND SUMMARY

The treatment of peripheral circulatory collapse or shock is described, with special reference to intra-arterial transfusion.

Experience of more than 100 cases suggests that intra-arterial transfusion is far superior to intravenous transfusion both in the treatment of established shock and as a preventive measure in operations where serious shock is expected.

Apparatus for intra-arterial transfusion should be immediately available in the operating-rooms and casualty departments of all hospitals, in advanced hospitals and field ambulances on active service, and in blood-banks and treatment centres of civil defence organisations.

I should like to record my gratitude to Dr. Lewis S. Carey and his associates for their careful experimental and clinical work on this problem, and to Dr. James H. S. Mahood, my anæsthetist, for his unfailing interest in the care of my patients, and his constant supervision of intra-arterial transfusions during and after operation.

ISONICOTINIC ACID HYDRAZIDE IN THE TREATMENT OF TUBERCULOUS MENINGITIS IN CHILDREN

HUDDERSFIELD AND HALIFAX HOSPITAL GROUPS

THERE is little doubt that the hydrazine derivatives of isonicotinic acid represent a further advance in the treatment of tuberculosis. The clinical results published so far appear to be confined to the treatment of chronic respiratory tuberculosis. This paper reports the provisional results of the treatment of four children with tuberculous meningitis with isonicotinic acid hydrazide (I.N.H.). All four patients have been followed up for 10 weeks. In one case treatment was stopped at 8 weeks, and in another at 9 weeks; treatment in the other two cases is continuing.

The following investigations were carried out before treatment and then at regular intervals:

Daily analysis of the urine and hæmoglobin estimation; twice-weekly full blood-counts, cerebrospinal-fluid (C.S.F.) analysis, and liver-function tests (alkaline phosphatase, thymol turbidity, and icteric index); and weekly blood-urea estimations. An electrocardiogram (E.C.G.) and a bone-marrow biopsy were made at 10 weeks in three of the cases.

CASE-REPORTS

Case 1.—A girl, aged 5½, was admitted in a stupor. 2½ years before, she had been given intrathecal and intramuscular streptomycin, together with *p*-aminosalicylic acid (P.A.S.) by mouth, intermittently for 3 months. She was reported to be physically and mentally normal on discharge; her C.S.F. still showed 10 cells, but was otherwise within normal limits. Follow-up was incomplete. She remained well until 10 days before readmission when she became listless, irritable, and increasingly drowsy.

On admission she could not recognise her parents, and lay curled up, actively resisting interference. Her C.S.F. contained 60 lymphocytes, 80 mg. of protein, and 38 mg. of glucose per 100 ml. Treatment was started with 0·05 g. of streptomycin intrathecally daily, 0·25 g. intramuscularly twice daily, and P.A.S. by mouth. The response was good, and after a month's treatment she appeared physically well. Mentally, however, she had regressed to the level of a child of 2–3 years. Early deafness was suspected which, in association with her mental state, made the further use of streptomycin undesirable, and treatment was stopped.

When I.N.H. became available a month later, treatment was restarted with 4 mg. per kg. body-weight daily by mouth in 6-hourly doses, increasing after 2 days to 8 mg. per kg. 8 weeks later, the C.S.F. still contained 36 cells, 100 mg. of protein, and 30 mg. of glucose per 100 ml. The dosage of I.N.H. was increased to 16 mg. per kg. A week later the C.S.F. had improved to 10 cells, 40 mg. of protein, and 42 mg. of glucose per 100 ml. She had been very active with an excellent appetite, but now she began to tire easily, her appetite failed, and vomiting and diarrhœa developed. Treatment was stopped and within a few days her symptoms had ceased. A week after stopping treatment her C.S.F. glucose had risen to 68 mg. per 100 ml.

Apart from slight deafness, the child remains physically well. There has been no obvious change in her mental state, which remains that of a child of 2–3 years. Laboratory tests revealed no abnormality other than a fall of hæmoglobin from over 100 to 85% a few days after the dosage of I.N.H. had been increased. The hæmoglobin quickly returned to over 100% when treatment was stopped.

Case 2.—A boy, aged 15 months, was admitted after 3 weeks' listlessness, anorexia, and loss of weight. He was extremely irritable with marked meningeal signs. The Mantoux reaction (1 : 1000) was positive. The C.S.F. findings were: 33 cells (80% lymphocytes), protein 250 mg., and glucose 18 mg. per 100 ml. X-ray examination of the chest was negative. Treatment was started with streptomycin 0·025 g. intrathecally daily and 0·25 g. intramuscularly twice daily with P.A.S. by mouth. Bacteriological proof of tuberculosis was obtained by guineapig inoculation. There was no response to treatment; the child's condition slowly deteriorated and the stiffness of the back and neck increased.

After a fortnight he was given I.N.H. (4 mg. per kg. daily in 6-hourly doses) in addition to the streptomycin and P.A.S. This was increased to 8 mg. per kg. after 2 days. 48 hours later a marked improvement became apparent; he took his food eagerly, and within a week he was sitting up in his cot playing with his toys. His appetite became voracious, and his weight increased at the rate of nearly 1 lb. per week. After 10 weeks the child appeared physically and mentally normal, save for some weakness of one arm. The glucose content of the C.S.F. became normal after 6 weeks, but the cells and protein remained raised (150 cells and 200 mg. of protein per 100 ml.) at 10 weeks. No other abnormality in the laboratory investigations has been found. The E.C.G. and bone-marrow examination were within normal limits at 10 weeks.

Case 3.—A girl, aged 2, was admitted with 3 weeks' history of anorexia, constipation, and fretfulness. The child was irritable, pale, and flabby. No other abnormal physical signs could be found. The C.S.F. contained 20 cells (all lymphocytes), 70 mg. of protein, and 47 mg. of glucose per 100 ml. The Mantoux (1 : 1000) was positive. X-ray examination of the chest showed nothing abnormal. Guineapig inoculation was finally positive.

Treatment was started with streptomycin and P.A.S., and there was some initial response, but during the 4th week the child's condition deteriorated. Intrathecal treatment became increasingly difficult. Streptomycin and P.A.S. were stopped, and I.N.H. (8 mg. per kg. daily) was given by mouth. A week later a slight but definite improvement was noted; the previously swinging temperature settled and the child began to take food by mouth. But this improvement was not maintained and at the end of a further 3 weeks streptomycin and P.A.S. were given in addition to I.N.H.

The child's condition continued to deteriorate, and she now presents the picture of decerebrate rigidity. The appearance was one of toxic rigidity; the legs were extended and plantar flexed, and the upper limbs were extended with the hands flexed at the wrists, the forearms pronated, and the fingers curved into the palms. All attempts at passive movements meet with great resistance. It is very doubtful whether therapy should be continued. Again laboratory tests showed no evidence of I.N.H. toxicity other than a temporary fall in hæmoglobin.

Case 4.—A girl, aged 6, was admitted after 6 days of constipation, anorexia, headache, and photophobia. On examination she was irritable but coöperative, and had marked meningeal signs. The C.S.F. contained 110 cells (90% lymphocytes), 80 mg. of protein, and 39 mg. of glucose per 100 ml. Tubercle bacilli were seen in a direct smear of the C.S.F. The mother was found to have open pulmonary tuberculosis.

Treatment was started with I.N.H. (8 mg. per kg. daily in 6-hourly doses by mouth). 3 days later she was symptom-free, her appetite being almost insatiable, and after a week she was running happily around the ward. Her weight increased at the rate of over 1 lb. per week for 5 weeks, after which it remained stationary. Her C.S.F. was within normal limits 8 weeks after the start of treatment (5 cells, 20 mg. of protein, and 60 mg. of glucose per 100 ml.). C.S.F. examination at 10 weeks showed 4 cells, 20 mg. of protein, and 50 mg. of glucose per 100 ml. A radiograph of the chest taken on admission showed no abnormality, and another taken 3 weeks later showed a hilar adenitis with no visible infiltration in the lung parenchyma.

After 8 weeks she complained of nausea and began to vomit after meals. The same day her liver-function tests became abnormal (thymol turbidity 7 units, alkaline phosphatase 24 King-Armstrong units, icteric index 11 units) and bile was present in her urine for the first time. Treatment was stopped. 2 days later she had a slight icteric tinge, and her liver became palpable for two fingers below the costal margin. Alkaline phosphatase had risen to 35 units, and thymol turbidity to 30 units. The vomiting stopped after 48 hours. A week later the jaundice had disappeared, the liver was no longer palpable, and the urine was free from bile. The liver-function tests improved quickly (thymol turbidity 15 units, alkaline phosphatase 15 units, icteric index 6 units). With the onset of nausea the child lost ¾ lb. in 2 days, but she regained it during the following week.

A month before, two children in the same ward had had infective hepatitis; two nurses in the ward also contracted it some time later. It seems that this child also had infective hepatitis—fortunately of a very mild degree.

Throughout treatment she remained fully coöperative. She never showed any signs or symptoms other than those associated with tuberculous meningitis or infective hepatitis. We observed none of the reactions such as headache, dryness of the mouth, hyperflexia, leg twitching, vertigo, constipation, reflex disturbances of micturition, or dyspnœa, which have been described during treatment with I.N.H. in adults (Selikoff and Robitzek 1952, Robitzek and Selikoff 1952). A gradual fall of 20% in hæmoglobin occurred during the first few weeks of treatment, but corrected itself without treatment during the following weeks. Except for the abnormal liver-function tests associated with an intercurrent attack of infective hepatitis, the other laboratory tests remained within normal limits. An E.C.G. and marrow biopsy at 10 weeks were also normal.

DISCUSSION

Four patients are too few and 10 weeks too short for any firm deductions to be made, but some points are worth noting.

Case 1 responded well to streptomycin clinically, but there was no improvement in the C.S.F. Streptomycin was stopped and I.N.H. substituted because of her deafness and mental condition. Only after the dosage of I.N.H. had been increased to 16 mg. per kg. did improvement in the C.S.F. occur. Treatment with the increased dose had to be stopped after a week because of intolerance.

Case 2 only responded to I.N.H. and streptomycin combined. Progressive clinical improvement was not, however, accompanied by improvement in the C.S.F., which remained very abnormal.

Case 3 showed only an initial response to streptomycin, and later to I.N.H. Later deterioration was uninfluenced by the two drugs in combination.

Case 4, the only child treated with I.N.H. alone, showed a dramatic response, and she was clinically well within a week. Treatment was stopped at 8 weeks because of intercurrent infection. This success is encouraging, and, though the possibility of relapse cannot be excluded, it seems unlikely. It is doubtful whether streptomycin could have produced such a rapid improvement, either clinically or in the C.S.F.

The contrast between the two forms of therapy could hardly be greater. Streptomycin requires a long course of intrathecal and intramuscular injections, distressing alike to patient, parents, and staff. I.N.H. on the other hand can be given by mouth as a pleasantly flavoured syrup and is eagerly taken.

The scheme of dosage of I.N.H. was devised more or less arbitrarily from the preliminary reports on its use in chronic pulmonary tuberculosis in adults and in animal experiments. No acute toxic effects were observed after 10 weeks on 8 mg. per kg. daily. One child showed signs of intolerance when the dose was increased to 16 mg. per kg., but these signs quickly disappeared when treatment was stopped. Chronic toxicity cannot be assessed in such a short time; it would be expected to affect mainly parenchymatous organs, notably the liver, kidney, and bone-marrow.

Rubin et al. (1952) showed that prolonged administration of I.N.H. in dogs resulted in fatty degeneration of the liver and in jaundice. In case 4 evidence of liver damage occurred after 8 weeks. This was almost certainly the result of an intercurrent attack of infective hepatitis from which the child made a good recovery. In retrospect, this attack of infective hepatitis could be regarded as fortuitous, for it showed that I.N.H. in the dosage used is unlikely to cause liver damage. If such damage was present it is improbable that the child would have had such a mild attack of infective hepatitis or made such a rapid recovery.

Analysis of the urine and weekly blood-urea estimations showed no evidence of renal damage. Urine concentration and dilution tests remained within normal limits. In each case a fall in the hæmoglobin occurred, varying from 10 to 25%, but this fall was seen to be reversible without stopping treatment. There were no significant changes in the white cells. Bone-marrow biopsies at 10 weeks showed a normal cellular tissue with the usual proportion of red and white blood-forming elements. Periodic pulse and blood-pressure readings and an E.C.G. at 10 weeks showed no deviation from normal.

SUMMARY

Four children with tuberculous meningitis were treated with isonicotinic acid hydrazide, either alone or combined with streptomycin, for a period of 8–10 weeks.

A child who had I.N.H. alone showed dramatic improvement, and became clinically well within a week. Her C.S.F. became normal in 8 weeks, and remained so for at least 2 weeks after stopping treatment.

The three other cases were treated initially with streptomycin and later with I.N.H., or with the two together. The results were equivocal.

There were no signs of drug toxicity, other than a temporary fall in hæmoglobin level, but signs of intolerance appeared when the dosage was increased to 16 mg. per kg. body-weight.

Our thanks are due to the resident medical and nursing staff, and also to the laboratory staffs in both Hospital Groups for their technical assistance.

ALKYLAMINES IN THE TREATMENT OF LEUKÆMIA

DEPARTMENT OF HÆMATOLOGY, MANCHESTER ROYAL INFIRMARY

Since the war-time investigations of Wilkinson, who as early as 1942 obtained remissions in chronic leukæmia by the intravenous administration of nitrogen mustards, many reports have been published about these compounds in leukæmia, Hodgkin's disease, and allied disorders. Owing to war-time restrictions, the original observations made here were not published until after the war (Wilkinson and Fletcher 1947), but earlier reports came from American workers (Goodman et al. 1946, Rhoads 1946, Jacobson et al. 1946). Since then the many reports on the therapeutic effects of nitrogen mustards have been conveniently summarised by Karnofsky (1948), Gellhorn and Jones (1949), Burchenal (1950), and Reinhard et al. (1950).

We have treated various diseases with the nitrogen mustard group of drugs in a large number of patients in this department of the Manchester Royal Infirmary; but we report here only our results obtained in 102 patients with leukæmia. In this relatively large series the long period of observation has enabled us to observe both the early and the late results of treatment, thus facilitating a better assessment of the therapeutic value of these alkylamines. In most of the cases published hitherto only the early results have been reported.

MATERIAL AND METHODS

The chemistry and pharmacology of the alkylamines have been extensively studied experimentally by British workers, many of the results remaining unpublished, and some post-war reviews have appeared (Gilman and Philips 1946, Anslow et al. 1947, Columbic et al. 1947a and b, Karnofsky 1948); and the investigations on the

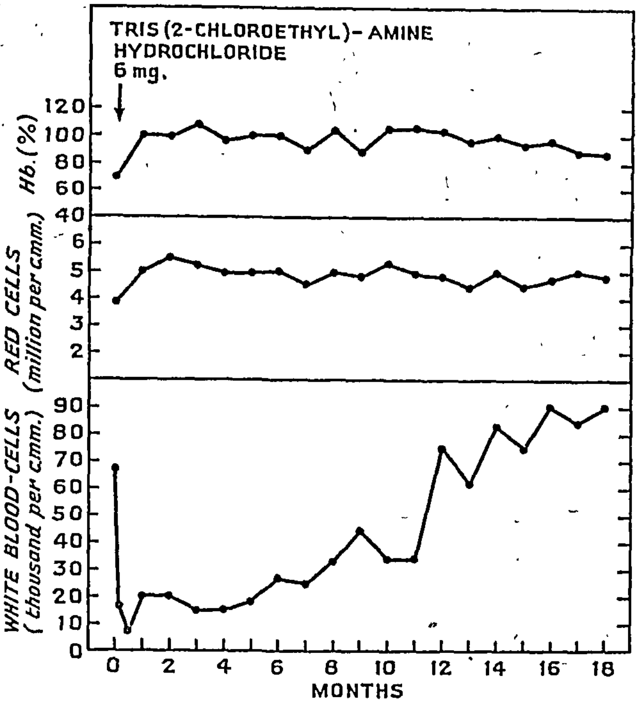

Fig. 1—Reduction in number of leucocytes after single injection of tris (2-chloroethyl)-amine hydrochloride 6 mg. in chronic lymphatic leukæmia.

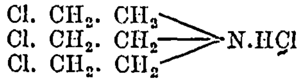
effects of mitotic poisons in general have been reviewed by Ahlström (1951).

In this series the "tris" compound, tris (2-chloroethyl)-amine hydrochloride



$$\begin{matrix}\mathrm{Cl.\,CH_2.\,CH_2} \\ \mathrm{Cl.\,CH_2.\,CH_2} \\ \mathrm{Cl.\,CH_2.\,CH_2}\end{matrix}\Big> \mathrm{N.HCl}$$

was used almost exclusively, for Wilkinson and Fletcher (1947) had previously found that this compound in their hands did not give any serious complications and was more convenient to handle than the "bis" derivative; other workers have preferred the latter.

We have already reported our results obtained in another series of cases treated with β-naphthyl-di-2-chloroethylamine ('R48;') orally and shown, that as a whole they were inferior to those obtained with the intravenous 2-chloroethylamines (Gardikas and Wilkinson 1951). In this paper we shall not consider further this oral therapy with R48.

Dosage

The standard single dose was 6 mg. of the tris (2-chloroethyl)-amine hydrochloride, but in a few cases we gave 6–12 mg. in a later course of treatment without any unusual or untoward effect. The treatment was given in courses, each course usually comprising 3–6 injections. The remissions did not always last the same time, and we awaited a relapse before giving the patient another course of treatment.

Our routine technique differs slightly from that of other workers, who give the injections on consecutive or alternate days. According to the initial blood-count and clinical state of the patient, we usually give the first two injections on the first and third days, although occasionally only the first one may be needed. With daily leucocyte-counts, and twice-weekly full blood-counts, no further treatment is given until the decrease in the number of leucocytes has ceased (from several days to two weeks in different patients). During this time the reaction can be watched, and then further treatment is given, if required, until the leucocyte-count is at the desired level. This type of control is, we feel, an essential precaution if the best results are to be obtained, since sensitivity to alkylamines varies greatly, and occasionally we have seen the leucocytes returning to normal after only one 6-mg. injection, as shown in fig. 1, while the patient experiences the minimal disturbance.

TABLE I—PARTIAL HÆMATOLOGICAL REMISSION OBTAINED IN FOUR CASES OF ACUTE LEUKÆMIA

Case no.	Type of acute leukæmia	No. of white cells per c.mm.		Amount of "tris" compound used (mg.)
		Before treatment	After treatment	
1	Myeloblastic	120,000	3700	6
2	Myeloblastic	140,000	6800	6
3	Lymphatic	64,000	13,000	16
4	Monocytic	55,000	1200	6

Clinical Cases

This series includes 20 patients with acute leukæmia, 50 patients with chronic myeloid leukæmia, and 32 patients with chronic lymphatic leukæmia.

RESULTS IN ACUTE LEUKÆMIA

The 20 patients with acute leukæmia were classified according to the morphological differentiation of the immature cells in the bone-marrow and the peripheral blood; there were 12 with acute myeloblastic, 4 with acute lymphatic, and 4 with acute monocytic leukæmia.

The results have been *disappointing*; a slight clinical improvement was obtained in 2 patients, but the remission lasted a very short time, and then the patient went rapidly downhill, as with all other forms of treatment. A partial hæmatological remission, in the sense that the white-cell count fell from a high level to normal or subnormal, was obtained in 4 cases (see table I).

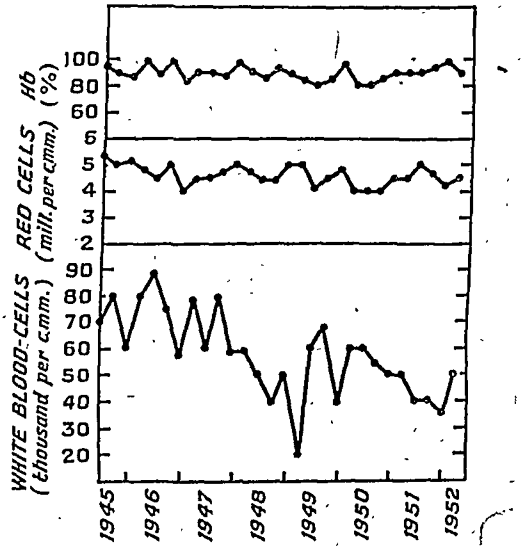


Fig. 2—A case of slowly progressive chronic lymphatic leukæmia in which the patient has remained well for years without specific treatment.

In spite of the considerable reduction in the number of leucocytes the *relative* numbers of blasts and other immature cells remained unchanged. In contrast to experience with folic-acid antagonists (Wilkinson and Gardikas 1951), A.C.T.H. and cortisone (Wilkinson and Gardikas, to be published), and urethane (Heilmeyer 1948), no case treated with the nitrogen mustard drugs showed complete hæmatological remission with the production of normal bone-marrow and blood picture.

RESULTS IN CHRONIC LEUKÆMIA

In this series 82 patients had chronic leukæmia; 50 having chronic myeloid leukæmia (25 men and 25 women.

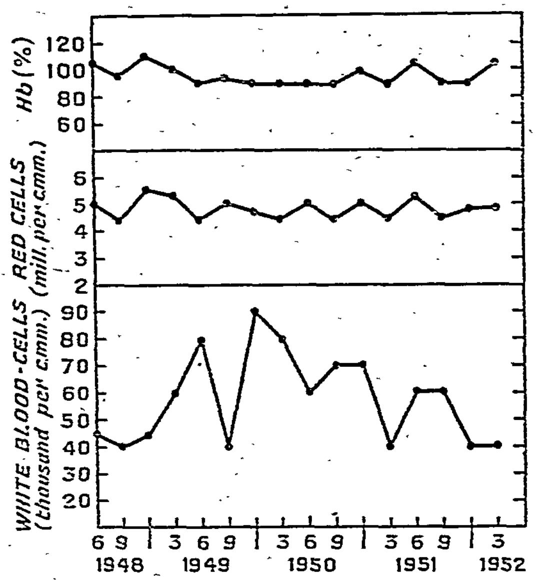

Fig. 3—Another case of slowly progressive chronic lymphatic leukæmia in which the patient has remained well for years without specific treatment.

aged 17–69), and 32 having chronic lymphatic leukæmia (23 men and 9 women aged 32–78).

Only progressive and severe forms of chronic leukæmia reaching a rather advanced stage were submitted to treatment, for we are of the opinion that treatment—and this applies to any form of treatment—should not be given until clinical symptoms and signs require it. Many patients, particularly with chronic lymphatic leukæmia, can and do get along for many years in fair or even good health with normal working capacity, the disorder remaining stationary or only progressing very slowly. This type should be referred to as the slowly progressive form of chronic leukæmia; the term "benign" type of leukæmia, which many workers use, seems to us inappropriate, since the ultimate issue is always fatal. Illustrative examples of this type of the disease are given in figs. 2–4. Most workers share our view, but Osgood (1951) has advocated treatment as soon as the diagnosis of leukæmia is established.

The main indication for the application of treatment is a poor or deteriorating general condition with constitutional symptoms—weakness, fatigue, loss of weight, pyrexia, and sweating. Severe anæmia—i.e., with Hb 60–70% (8·8–10·3 g. per 100 ml.)—constitutes per se an indication for treatment. Severe splenomegaly, even when other indications are not present, should also be considered as an indication, not only because of the "mechanical" disability it causes to the patient but also because the leukæmic process tends to take, sooner or later, a "malignant" course in patients with big spleens if no therapy is given. The same applies to severe lymph-node enlargement. The leucocyte-count, on the other hand, is not per se an indication for treatment. Patients with high leucocyte-counts—e.g., 60,000–100,000 per c.mm.—may be left without treatment, provided that other indications are absent. Conversely, a low leucocyte-count is not a contra-indication for treatment, since "subleukæmic" or "aleukæmic" forms are not synonymous with mild forms, and the peripheral picture does not reflect the activity of the leukæmic process.

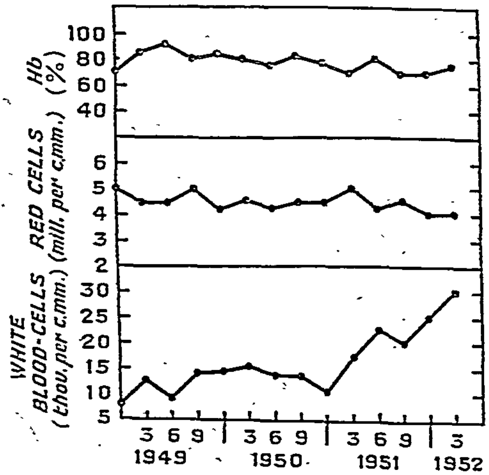

Fig. 4—A case of slowly progressive chronic myeloid leukæmia in which the patient has remained well for years without specific treatment.

No further treatment is given to the patients until they show clinical or hæmatological relapses, and for this reason we keep all our patients under regular and frequent supervision, seeing them at least monthly.

42 of the 50 patients with chronic myeloid leukæmia and 26 of the 32 with chronic lymphatic leukæmia showed a satisfactory remission after the first course of treatment.

Blood-count

A considerable fall took place in the total leucocyte-count after the treatment, the leucocyte-count returning to within the normal range or to a predetermined level by appropriate adjustment of the dose.

TABLE II—RESPONSE OF SIGNS AND SYMPTOMS FOLLOWING NITROGEN MUSTARD THERAPY IN 82 CASES OF CHRONIC LEUKÆMIA

Sign or symptom	No. of patients in whom symptom or sign was present before treatment	After treatment		
		Relieved		Unrelieved
		Completely	Partially

	L 21	19	..	2
		Gain	No change	Loss
Loss of weight ..	M 48	34	6	8
	L 30	20	6	4

M, chronic myeloid leukæmia.
L, chronic lymphatic leukæmia.

The immature cells in the peripheral blood were much reduced in number or completely disappeared.

There was often a correction of the anæmia, even without blood-transfusions in some cases; thus the hæmoglobin levels, which were low before the start of treatment in 62 patients, showed a definite rise in 44, remained unaltered in 8, and fell in 10 of these patients. This improvement of the anæmia was less often observed in chronic lymphatic leukæmia; thus only 6 of 18 patients who had severe anæmia before treatment showed significant increase in the hæmoglobin levels after treatment, whereas of 44 similar patients with chronic myeloid leukæmia the hæmoglobin levels improved considerably in 38.

Spleen and Lymph-node Enlargement

In 45 of 50 patients with chronic myeloid leukæmia a considerable splenomegaly was present before the start of treatment; after treatment splenomegaly regressed completely, the spleen becoming impalpable in 20 patients, partially palpable in 22, and practically unchanged in 3.

Of 15 patients with chronic lymphatic leukæmia and considerable splenomegaly the splenic enlargement disappeared completely in 5 and partially in 8, and remained unchanged in 2.

Severe lymph-node enlargement, which was present before the start of treatment in all 32 patients with chronic lymphatic leukæmia, disappeared completely in 10, diminished in 19, and remained unchanged in 3 (see table II).

Constitutional Changes

Most of the patients showed much improvement in appetite, increase in weight, and return of energy and vitality. Nocturnal sweats and pyrexia, if present, often disappeared, and in many cases the patient regained normal or almost normal working capacity (see table II).

The response is independent of the duration and, to a great extent, of the severity of the disease. Dramatic responses have been obtained even in apparently moribund patients.

Length of Remissions

The length of remissions—i.e., the length of period between two successive courses of treatment—varied widely, as table III shows.

The remissions were followed by hæmatological and clinical relapses with reappearance of one or more of the initial symptoms. The subsequent courses were equally effective, but in the prolonged treatment the response appeared to become less pronounced, and finally a more or less refractory stage was reached and the patient went rapidly downhill.

TABLE III—DURATION OF REMISSIONS

Duration (mos.)	No. of cases	Duration (mos.)	No. of cases
> 24	1	4–6	20
13–24	6	1–3	40
7–12	9	<–1	6

TOXIC EFFECTS

Toxic effects may be local or general; the latter can be subdivided into immediate and late.

Local toxic effects are usually due to errors in technique. If the solution infiltrates the tissue round the veins, a severe and possibly necrosing inflammation may result locally. No accident of this kind was encountered in our series. Local thrombophlebitis may develop, but a good dilution of the solution will minimise its incidence. In spite of the very large number of nitrogen mustard injections that we have administered, we have had only a very few cases of phlebosclerosis, and these have been of quite moderate degree without constitutional symptoms, and have subsided with rest within a few days (table IV).

Immediate general toxic effects are usually nausea, anorexia, and vomiting, which were noted after about 30% of the injections; in most cases they were mild, and only in 2% of these cases was the reaction severe, with some vomiting for 24–48 hours accompanied by prostration; in no case were the gastro-intestinal disturbances so severe as to necessitate discontinuance of treatment. Anti-histamine drugs of the 'Dramamine' or 'Avomine' type were tried because of evidence of their good effect in controlling motion sickness; one tablet (25 mg.) was given immediately after the end of the injection, and another tablet four hours later. Our impression was that these were helpful, but their real value was difficult to assess accurately.

TABLE IV—COMPLICATIONS OF NITROGEN MUSTARD TREATMENT OBSERVED IN 408 COURSES OF TREATMENT (EACH COURSE COMPRISING 2–7 INJECTIONS OF THE "TRIS" COMPOUND)

Complication	Frequency (%)
Moderate nausea	20
Moderate nausea and vomiting	12
Severe vomiting	2
Phlebosclerosis	2
Fever and rigor	0·4
Agranulocytosis (temporary and symptomless)	0·5

Late general toxic effects belong almost exclusively to the hæmopoietic system and could be described as a mere extension of the therapeutic effect of these substances. Severe leucopenia, with leucocyte-counts as low as 700–800 per c.mm., has only very occasionally been encountered after a course of treatment; with such leucopenia the patient has not felt disturbed or presented any constitutional symptom due thereto, and the leucocytes have rapidly returned to normal spontaneously. Severe complications or fatalities attributable to the treatment were not observed in this series. In table IV there is a brief summary of the observed complications and their frequency.

DISCUSSION

The present study shows that the tris (2-chloroethyl)-amine hydrochloride, though of no value in the treatment of acute leukæmias, can induce a satisfactory remission of clinical and hæmatological manifestations in many cases of chronic myeloid and chronic lymphatic leukæmias; and that, when it is given in the recommended dosage of 0·1 mg. per kg. of body-weight per single injection and under sufficient hæmatological control, the side-effects are not to be feared.

Naturally, at this stage, there arises the question of the relative value of nitrogen mustard treatment compared with other forms of therapy, especially irradiation. That the nitrogen mustard treatment presents certain advantages is obvious; it is inexpensive and easily administered, and it can be, and has usually been, given in an outpatient clinic, except for the first course, which is best initiated under hospital conditions and laboratory control. Further, since the therapeutic effect appears rapidly, the toxicity of the drug can be controlled more precisely than irradiation; and finally, while on treatment, the patient continues under his physician's care.

When, however, the question of the comparative value of the nitrogen mustard treatment is discussed, in most of the reports so far published the opinion is expressed that irradiation is by far superior in the management of chronic leukæmias, and the view is put forward that nitrogen mustards should only be given either in cases which, after a long period of irradiation, are refractory to it, or in cases which from the beginning do not seem to respond to irradiation.

Our impression with the nitrogen mustards has been quite to the contrary; and, since we have obtained impressive, often dramatic, results with persistent frequency, a comparison of our data with those available in published reports dealing with other forms of treatment may give us some more information.

The value, however, of such a comparative study is very limited; the published data are inadequate, since they deal mostly with average survival-rates since the onset of the disease, and very few statistical studies mention average survival-rates since treatment began. The number of patients in each series is relatively small, and for a disease with a protean clinical course like leukæmia this is a serious drawback. Pitfalls are numerous, and an example of the need for caution in drawing conclusions may be opportune at this place. If we compare the average survival-rate since the onset of the disease in the two groups of our cases of chronic myeloid leukæmia—the group of those treated with nitrogen mustard and the group who received no treatment—it will be seen that the corresponding figures for these two groups are 44·8 and 13·4 months. This finding, however,

TABLE V—AVERAGE SURVIVAL-RATE SINCE ONSET IN CHRONIC LEUKÆMIA TREATED BY VARIOUS METHODS

Reference	No. of cases	Treatment	Average survival (yr.)

loses much of its importance since one could reasonably argue that the second group—the untreated patients—includes some who were, when seen, desperately ill and who, because of this, did not receive treatment. So far as we know, no study has been published in which alternate cases without selection were treated by one form of therapy or another; and it is, of course, clear that this method alone, applied to large numbers, would provide accurate information for the comparative value of various forms of treatment.

Though a comparative study of the therapeutic effect of various forms of treatment is of limited value if not computed on the above-mentioned basis, we have attempted in the following section to compare our results, obtained with the alkylamines, with those obtained by various workers using other forms of treatment.

In the group of patients with chronic leukæmia who received alkylamine treatment and who have been followed up until death there are 42 patients with chronic myeloid leukæmia and 24 with chronic lymphatic leukæmia. In table V the average survival-rate since symptoms began in these patients is given, together with the average survival-rate given by other workers in similar series receiving other forms of treatment. In table VI the average survival-rate since the start of treatment is given. It will be noted that the results of treatment with the nitrogen mustard (2-alkylamine) are at least equal to those of treatment with P^{32} and with irradiation.

Statistical studies dealing with the degree of improvement following application of a form of treatment have not been published except one by Bethell (1943) who treated by irradiation 104 patients with chronic myeloid leukæmia. He classified his results as follows:

Excellent, if remission lasted more than 12 months.

Very good, if clinical and hæmatological improvement lasted 6–12 months.

Good, if clinical and hæmatological improvement lasted 3–6 months.

Fair, if there was transient clinical improvement but no real remission.

TABLE VI—AVERAGE SURVIVAL-RATE SINCE START OF TREATMENT IN CHRONIC LEUKÆMIA

Reference	No. of cases	Treatment	Average survival (yr.)
Myeloid leukæmia :			
Hoffman and Craver (1931)	71	Irradiation	2·6

Wintrobe and Hasenbush (1939)	23	Irradiation	1·68*
Gardikas and Wilkinson (1952)	42	Nitrogen mustard	2·25
Lymphatic leukæmia :			
Vogt (1949)	65	Irradiation	1·6
Gardikas and Wilkinson (1952)	24	Nitrogen mustard	2·1

* Since diagnosis was established.

In table VII our results with 50 cases of chronic myeloid leukæmia treated with nitrogen mustard are compared with Bethell's treated by irradiation, his criteria of classification being used.

In conclusion, it is clear that the alkylamines are powerful therapeutic agents in the treatment of chronic leukæmia; the simplicity of their administration and their numerous advantages have been emphasised. In our material the remissions were impressive in most of the patients, and in some of them the results were even dramatic. Most of the patients were enabled to lead a normal, or almost normal, life for a long time without much discomfort or disability. Further, a review of the published cases and a comparison of our results obtained with alkylamines and those obtained by other workers using other forms of treatment, such as deep irradiation and radioactive phosphorus, casts doubts on the view held by some that the latter kinds of treatment are superior to the alkylamines.

SUMMARY

102 patients with leukæmia were treated with intravenous chloralkylamines (nitrogen mustard). There were 20 cases with acute leukæmia, 50 with chronic myeloid leukæmia, and 32 with chronic lymphatic leukæmia.

TABLE VII—RESULTS OBTAINED IN 50 CASES OF CHRONIC MYELOID LEUKÆMIA TREATED WITH NITROGEN MUSTARD COMPARED WITH BETHELL'S 104 CASES TREATED BY IRRADIATION. BETHELL'S CRITERIA ARE USED

Results	In Bethell's (1943) series (%)	In present series (%)
Excellent	12·5	24·0
Very good	41·3	22·0
Good	36·5	36·0
Fair	7·7	12·0
No effect	1·9	6·0

The therapeutic results in the acute leukæmias were completely disappointing.

Of the 82 patients with chronic leukæmia, good clinical and hæmatological remissions were effected in 61.

The length of remissions—i.e., the interval between two successive courses of treatment—varied: in 1 patient it was more than 24 months; in 6 patients 13–24 months; in 9 patients 7–12 months; in 20 patients 4–6 months; in 40 patients 1–3 months; and in 6 patients either less than 1 month or absent. With careful dosage the toxic effects were infrequent and, as a rule, of little severity.

In 42 patients with chronic myeloid leukæmia treated with 2-chloralkylamine (nitrogen mustard) and followed up to death, the average survival from the onset of the disease was 3·7 years, and the average survival from the start of treatment 2·25 years; in 24 patients with chronic lymphatic leukæmia the corresponding figures were 3·6 and 2·1 years respectively.

From a comparison of our results obtained with 2-chloralkylamines with those already reported by several workers using X-ray irradiation and radioactive phosphorus, these chemotherapeutic methods seem to offer equally effective scope in the treatment of chronic leukæmias.

Part of this work was done during the tenure of the Sybil Mary Pilkington Fellowship by one of us (C. G.); and our thanks are due to the Trustees of that Fund for support, and to the Crookes Laboratories Ltd. for kindly supplying tris(2-chloroethyl)-amine.

CHLORAMPHENICOL IN ACUTE SHIGELLA DYSENTERY

A. J. S. McFADZEAN
M.B. Glasg., M.R.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF HONG-KONG

PETER D. STEWART
M.B. Edin.
MAJOR, R.A.M.C., PATHOLOGIST

ALTHOUGH sulphonamide derivatives are well established as the drugs of choice in the treatment of shigella dysentery, general agreement has not been reached about which is the most effective sulphonamide. We subscribe to the opinion that the soluble and easily absorbed sulphadiazine is more effective and consequently preferable to sulphaguanidine and succinylsulphathiazole. There are, however, drawbacks and limitations to sulphonamide therapy, especially treatment with sulphadiazine: (1) there is the risk of drug toxicity; (2) there is the danger of initiating therapy in cases with dehydration, with consequent delay in starting treatment; and (3) sulphonamide-resistant strains develop, leading to relapse, chronic dysentery, or increase in the carrier state.

In view of the demonstration of the sensitivity of shigella organisms to chloramphenicol in vitro and the report of Ross et al. (1950), among others, of the efficacy of chloramphenicol in the treatment of shigella dysentery in children, it was thought desirable to determine its value in shigella dysentery in adults.

MATERIAL AND METHODS

96 cases of shigella dysentery occurring in Hong-Kong from January to December, 1951, were treated with chloramphenicol. The control series consisted of 92 cases occurring within the same period and treated with sulphadiazine. In our opinion it is important that the controls should be cases occurring in the same period, for different factors may cause the severity of the dysentery to vary from year to year.

The age and sex distribution are set out in table I. In both groups the average duration of symptoms before admission was forty-eight hours.

On admission the stool was examined microscopically, and those patients whose stools showed "typical bacillary exudate" were selected for treatment. Treatment was started pending bacteriological report, and only the cases proved bacteriologically are included in this report. The bacteriological findings in both groups are set out in table I, from which it will be seen that *Shigella flexneri* was the most common organism.

Cases were classified as mild to moderate, severe, and severe with dehydration, according to clinical assessment based on the degree of toxæmia, the severity of the dysenteric symptoms, and clinical and laboratory evidence of salt and water deficiency. The distribution of cases in both groups is set out in table I. The routine management of all the cases was the same. Where salt and water deficiency existed, physiological saline solution and 5% glucose were given intravenously until the urinary chlorides were within normal limits and the eight-hour output of urine was at least 500 ml. During the later phase of restoration of extracellular volume a solution of potassium salts was added to the infusion. In cases which initially showed dehydration in the group treated with sulphadiazine, treatment was not started until the urinary volume was restored. This delay was not necessary with chloramphenicol.

The patients treated with chloramphenicol were given an initial loading dose of 30 mg. per kg. of body-weight, and thereafter 30 mg. per kg. of body-weight daily in divided doses four-hourly. This was continued for three days after the first negative stool culture. The patients in the control group were given 2 g. of sulphadiazine and thereafter 1 g. four-hourly for three days after the first negative stool culture or until a total of 38 g. had been administered.

Stool cultures were made daily until three consecutive negative findings were obtained. When no stool was passed, specimens were obtained by rectal swab through a short proctoscope. Thereafter all stools passed were examined bacteriologically until discharge from hospital. The initial medium used was desoxycholate citrate agar. In all cases the medium was inoculated immediately the stool was passed or the swab taken.

Sigmoidoscopy was done in all cases after cessation of the acute diarrhœa.

The conditions of employment of 20 patients in the chloramphenicol-treated group and of 10 in the sulphadiazine-treated group were such as would lead to any relapse being brought to our notice. 74 of the remaining 76 in the chloramphenicol group and 75 of the remaining 82 in the sulphadiazine group reported for follow-up examination eight weeks after discharge from hospital.

RESULTS

Bacteriological Findings

The time which elapsed in both groups between the start of treatment and the first negative bacteriological report, with daily specimens, is set out in table II. In no case in either group was the organism isolated subsequent to the first negative report. In 22 of the 72 cases in the chloramphenicol-treated group with negative stools within twenty-four hours, each stool passed in that period was examined bacteriologically. The average time required for disappearance of the organism was sixteen hours.

It should be noted that in the sulphadiazine-treated group in 9 of the 11 cases showing evidence of salt and water loss there was a delay of twelve to twenty-four hours before treatment with sulphadiazine.

Table II shows that the stools of all the patients treated with chloramphenicol were bacteriologically negative four days after the start of treatment. In the sulphadiazine-treated group 9 patients had positive stool cultures at the end of the course of 38 g. six days after the start of treatment. Only 1 of these patients had a previous history of "diarrhœa," which had been treated with sulphaguanidine some two years previously. In 8 of the

TABLE I—DISTRIBUTION, SEVERITY, AND BACTERIOLOGICAL FINDINGS

Treatment	No. of cases	Age (yr.)			Sex		Severity			*Shigella*			
		15–25	25–35	35–50	M	F	Mild to moderate	Severe	Severe with dehydration	*flexneri*	*sonnei*	*Schmitzii*	Untyped*
Chloramphenicol ..	96	36	42	18	72	24	49	22	25 (5 critically ill)	70	14	1	11
Sulphadiazine ..	92	41	40	11	69	23	65	16	11	71	5	2	14

*In the earlier part of the investigation an adequate supply of typing sera was not available.

9 cases in-vitro sensitivity tests showed the organism to be highly resistant to sulphadiazine. Chloramphenicol was given, and this led to negative stool cultures in twenty-four hours in 4 cases, in forty-eight hours in 3 cases, and in ninety-six hours in 1 case. An in-vitro sensitivity test was not made in the 9th case, but a second course of sulphadiazine led to negative stool cultures after forty-eight hours.

Clinical Findings

In all the cases treated with chloramphenicol the fever resolved within twenty-four hours, and coincidentally there was much improvement in subjective symptoms. In the group treated with sulphadiazine fever resolved on average in 2·2 days, and resolution of subjective symptoms was less dramatic. Diarrhœa was considered to have ceased when three or less semi-formed or formed normal stools were passed. This occurred in the chloramphenicol group on average in 3·5 days, and in the sulphadiazine group in 5·6 days. The average time required for macroscopic blood to disappear from the stools was 1·5 days in the chloramphenicol-treated group and 3·6 days in the sulphadiazine-treated group. Sigmoidoscopy, done on average six days after the start of treatment, showed no significant difference between the two groups.

Dosage

The average total dose of chloramphenicol was 9·5 g., the individual doses ranged from 7·75 to 16 g. Treatment with sulphadiazine was discontinued because of toxic complications in 2 cases on the fourth and fifth days. Both patients had bacteriologically negative stools, and neither case relapsed.

Relapses

No relapses were encountered in either group.

Toxic Complications and Side-effects

In the chloramphenicol-treated group 5 patients developed mild glossitis and 4 pruritus ani. The symptoms and signs rapidly resolved when chloramphenicol was withheld. In the sulphadiazine-treated group indications requiring prompt cessation of treatment were encountered in 2 cases: 1 patient had severe hæmaturia on the 4th day, which in our opinion was occasioned by inadequate supervision of urinary output; and the other patient developed acute intravascular hæmolysis with hæmoglobinuria.

TABLE II—COMPARISON OF CHLORAMPHENICOL THERAPY WITH SULPHADIAZINE THERAPY

Treatment	24 hours		2 days		3 days		4 days		5 days		6 days	
	No. negative	No. remaining positive	No. negative	No. remaining positive	No. negative	No. remaining positive	No. negative	No. remaining positive	No. negative	No. remaining positive	No. negative	No. remaining positive
Chloramphenicol (96 cases)	72	24	17 72 89	7	4 89 93	3	3 93 96	Nil				
Sulphadiazine (92 cases)	19	73	42 19 61	31	19 61 80	12	2 80 82	10	1 82 83	9	..	9

DISCUSSION

Table II shows that the pathogens disappeared from the stools more rapidly in the chloramphenicol-treated group than in the sulphadiazine-treated group. This confirms the observation of Ross et al. (1950), reporting on chloramphenicol in the treatment of 35 cases of shigella dysentery (33 *Shigella sonnei*, 2 *Shigella flexneri*) in children aged from 3 months to 7 years, that the stools became bacteriologically negative on average in 0·76 day. These workers had previously treated 20 cases with sulphadiazine and found that the stools became negative on average in 2 days. Using the rapidity of disappearance of pathogens as the therapeutic index they considered that there was no statistically significant difference between the two groups. In our series a significant difference does emerge. Within four days all of the chloramphenicol-treated group had negative stool cultures, whereas in the control group 9 cases remained positive six days after the start of sulphadiazine therapy, when a total dosage of 38 g. had been given.

Further, not only was bacteriological improvement more rapid in the chloramphenicol-treated group but also the patients' clinical progress. Fever resolved more rapidly, as did the dysenteric symptoms. Abnormal constituents in the stools disappeared earlier than in the controls.

The persistent pathogens in 8 of the 9 cases treated with sulphadiazine were shown in vitro to be highly resistant to sulphadiazine. Treatment with chloramphenicol led to their rapid removal. This confirms the observations of Cooper and Keller (1950), who reported rapid resolution with chloramphenicol of 4 cases of dysentery in children due to sulphadiazine-resistant *Shigella sonnei*. These workers also reported the disappearance of sulphadiazine-resistant *Shigella sonnei* from the stools of an adult carrier after treatment with chloramphenicol.

Perhaps the happiest aspect of the use of chloramphenicol in acute bacillary dysentery is the relaxation of the rigid supervision of urinary output so essential in patients receiving sulphadiazine. Further, the use of chloramphenicol allows treatment to be started at the earliest moment, even in cases of salt and water deficiency, whereas the administration of sulphadiazine may require to be delayed until the urinary output is satisfactory.

SUMMARY AND CONCLUSIONS

Chloramphenicol is a very efficient agent in the treatment of acute shigella dysentery. It is also effective in the treatment of sulphadiazine-resistant pathogens.

It is more efficient than sulphadiazine, which is regarded by many as the sulphonamide of choice, for the following reasons: (1) resolution, bacteriological and clinical, is more rapid; (2) resistance to chloramphenicol has not been encountered, whereas sulphadiazine resistance has a significant incidence; and (3) treatment can be started in the presence of salt and water deficiency.

We have pleasure in expressing our appreciation of the able assistance of Lieut.-Colonel A. C. S. Hobson, R.A.M.C., and Captain D. Fraser, R.A.M.C., who supervised clinically some of the present cases.

ACUTE COLONIC OBSTRUCTION DUE TO PANCREATITIS

D. C. MILN
M.B. Glasg., F.R.F.P.S.
SURGEON TO OUTPATIENTS

T. H. C. BARCLAY
M.B. Glasg., F.R.F.P.S.
SENIOR REGISTRAR

GLASGOW ROYAL INFIRMARY

THE colon may be obstructed by pressure from pathological neighbouring structures, and this usually happens at those sites where the large bowel is fixed—i.e., at the flexures—and in the pelvis, where the recto-sigmoid loop may be occluded by a large inflammatory mass or by adhesions due to previous inflammation.

Two patients were recently admitted to this hospital with acute obstruction of the colon due to pressure from an inflammatory mass at the splenic flexure. The masses proved to be due to pancreatitis.

CASE-RECORDS

Case 1.—A man, aged 73, was admitted to hospital on Aug. 11, 1951, with four days' history of colicky central abdominal pain with nausea but no vomiting, several years' history of constipation, and eight days' history of stoppage of the bowels. He had lost about 35 lb. in weight in a year.

Examination.—He was very thin, weighing just under 98 lb., and dehydrated. His respirations were shallow and mucosæ pale. His pulse-rate was 92 and pulse bounding and regular. His blood-pressure was 180/80 mm. Hg. His heart sounds were of moderate quality, with a systolic murmur at the apex. His abdomen exhibited gross central and right peripheral distension, with much tympanicity to percussion centrally but shifting dullness in the flanks. The abdominal wall over the subumbilical region was œdematous. There were generalised guarding and tenderness over the abdomen, with no apparent localisation. The rectum was ballooned.

Treatment.—Two gentle soap-and-water enemata were given on admission, without producing either fæces or flatus. As the urinary chlorides were deficient, treatment with intravenous glucose-saline solution was begun.

Operation.—About five hours after admission laparotomy through a left lower paramedian incision showed that the peritoneal cavity contained purulent fluid. The small bowel, cæcum, and colon were distended as far distally as the splenic flexure, but beyond this the large intestine was collapsed and empty. At the splenic flexure a mass was palpable, but it was difficult to determine whether this was malignant or not, because it was enclosed in omentum. In view of the patient's poor general condition and peritonitis, proximal drainage through a cæcostomy was instituted, and the abdomen was closed round a drainage tube to the pelvis.

Postoperatively the patient's condition remained poor for seven days, but with restoration of his electrolyte balance and with antibiotic therapy it slowly improved. A high-protein diet was prescribed, and within five weeks his weight had increased to 120 lb.

Further Operation.—On Oct. 11 laparotomy through a left subcostal incision showed that the palpable mass found at the previous operation was still present and incorporated the spleen, the splenic flexure, omentum, and the tail of the pancreas. Mobilisation of the mass, with splenectomy and removal of the omentum and the tail and part of the body of the pancreas, revealed the splenic flexure to be free from obstruction. The continuity of the colon was not disturbed. During the dissection the pancreas was found to be necrotic over a wide area. The abdomen was closed.

Operation Specimen.—The tissue removed at operation consisted of spleen, omentum, and a portion of pancreas. The pancreas presented numerous areas of fat-necrosis and hæmorrhage. The spleen showed a moderate degree of perisplenitis. The portion of omentum examined showed severe fat-necrosis.

Postoperatively the patient's condition immediately after the operation was satisfactory, but after forty-eight hours he became collapsed and cyanosed, and showed evidence of peripheral circulatory failure. His pulse-rate rose to 130 and his blood-pressure fell to 100/68 mm. Hg. His pupils became unequal, the left becoming dilated. No other abnormality of the central nervous system was detected. He became comatose and died.

Necropsy Findings.—The heart was enlarged and showed left ventricular hypertrophy. There was no valvular disease, but the myocardium was of poor quality. The aorta and coronary vessels exhibited patchy atheroma. The lungs showed terminal hypostatic pneumonia. No obstruction was found in the intestine. The remnant of the pancreas showed fat-necrosis. There was a massive hæmorrhage into the left suprarenal gland. The right adrenal showed no macroscopic abnormality. The brain showed only œdema, with no focal lesion to explain the ante-mortem inequality of the pupils.

Case 2.—A carter, aged 71, was admitted to hospital on Sept. 22, 1951, complaining of progressive weakness over the last few days, with severe recurrent generalised abdominal colic and vomiting for thirty-six hours. There had been no bowel movement for twenty-four hours.

Examination.—He appeared toxic and dehydrated, with a dry furred tongue, pulse-rate 94, volume of pulse moderate, heart sounds fairly good, abdomen distended and tympanitic, with generalised tenderness, maximal over the epigastrium, which showed muscle guarding. Very active bowel sounds were heard on auscultation. Digital examination revealed an empty and slightly ballooned rectum.

Operation.—After intravenous therapy to combat dehydration and electrolyte imbalance, the abdomen was opened, under general anæsthesia, through a right rectus-splitting incision. The cæcum and ascending and transverse colon were much distended, but the ileum showed only minimal dilatation. Obstruction was due to a fixed mass close to the splenic flexure. Cæcostomy was done.

Postoperative recovery was good, with continuation of intravenous fluid therapy. On Oct. 8, the bowel moved per rectum, and a barium enema revealed normal passage of contrast medium to the cæcum without any evidence of blockage or neoplasm. On Oct. 12, the patient developed retrosternal pain and appeared ill. He said he had had several similar attacks before his present illness, and electrocardiography showed coronary insufficiency. Convalescence was satisfactory, and on Nov. 6 laparotomy was done. A fibrotic omentum was found wrapped round the transverse colon, and areas of fat-necrosis were numerous. The pancreas was nodular and indurated and showed areas of fat-necrosis. The tail of the pancreas and the omentum were adherent, and were separated from the colon, which then showed no obstruction. A specimen of omentum showed fat-necrosis. There was no evidence of biliary disease. The cæcostomy and abdomen were closed, and recovery has been uneventful. He remains well to date.

COMMENTS

The secondary involvement of contiguous viscera from inflammation of the pancreas has often been described, but it is uncommon for the presenting secondary condition to be so severe that the primary cause is completely masked. The two cases reported here exhibited an almost identical clinical picture, no feature of which, even at the first operation, suggested that the pancreas was at fault. The patients were both old men. There was no history of dyspepsia or of biliary upset, and both patients appeared to have acute intestinal obstruction.

The complications of pancreatitis are many and varied, but implication of the colon is uncommon, though an abscess may rupture into the lumen (Aird 1949). Obstruction of the lumen of the colon is, however, very rare, and we can only trace three published cases; all concerned the splenic flexure:

Forlini (1927) reported a man, aged 38, who died of acute colonic obstruction after a 15-month history. Necropsy revealed that the cause of the occlusion was fibrosis following pancreatitis.

Remington et al. (1947) added two further very similar cases, one in a man aged 45, and the other in a woman aged 44, which presented with chronic colonic block and a history of proved pancreatitis of many years' duration. Both patients were successfully treated by excision of the tail of the pancreas and the occluded segment of colon.

Of our patients, the first had acute obstruction following a long chronic disease, and the second had a primary acute attack which must have been due to œdema and matting of pancreas and omentum to colon, this subsiding spontaneously on relief of the intestinal obstruction.

Thanks are due to Mr. G. T. Mowat, in whose wards these cases were, for permission to publish, and to Prof. G. L. Montgomery for pathological reports.

THE ASSESSMENT OF MOBILITY IN JOINTS

P. O. Williams
M.A., M.B. Camb.
REGISTRAR, DEPARTMENT OF RHEUMATISM, ROYAL FREE HOSPITAL, LONDON

In patients undergoing treatment for rheumatoid arthritis the methods of assessing improvement are unsatisfactory.

One of the most useful objective measurements of improvement is the change in range of movement of a joint. In the past this has usually been measured with a protractor to which two arms are attached and laid along the parts of the limb comprising the joint. This way of measuring the angle of movement has in practice the following disadvantages:

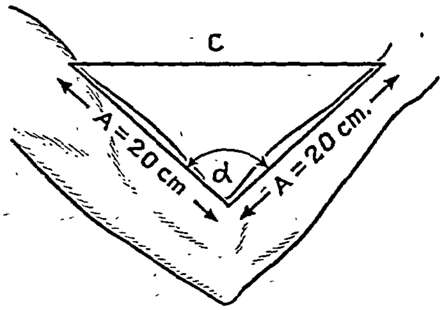

Fig. 1—Hypotenuse used at elbow-joint.

(1) With movement of the joint, muscle masses tend to interfere with correct measurement of the angle.

(2) Swelling of the joint or periarticular tissues—e.g., an olecranon bursa—may interfere with the position of the protractors.

(3) In joints where it is impossible to lay the protractor arms along straight edges the correct position of the protractor arms can only be determined by eye and is hence open to considerable inaccuracies. This is true of the knee, shoulder, and hip.

In this paper I give an account of a simple method of determining the angle of movement of a joint which avoids all the above difficulties. In the following description it is applied to the elbow.

Two points 20 cm. from the crease at the bend of the elbow are marked on the upper arm and on the forearm (fig. 1). The distances (C) between these points in full extension and flexion are measured and compared. This distance C varies with the angle of movement of the joint, according to the formula

$$\cos\alpha = 1 - \frac{C^2}{2A^2}$$

As C and A are known, a graph can be plotted (fig. 2) showing the relation of the angle α to the length C. From this graph the angle of movement of the joint can be read off directly when the distance C is known.

TABLE I—APPLICATION OF METHOD

Joint	Movement	Position of axis	Distance from and position of skin crease
Elbow	Flexion in full supination	Arm and forearm	In cubital fossa 20 cm.
Shoulder	Abduction with palm facing side of body	Arm and side of body	In axilla 30 cm.
Knee	Flexion	Thigh and leg	In popliteal fossa 30 cm.

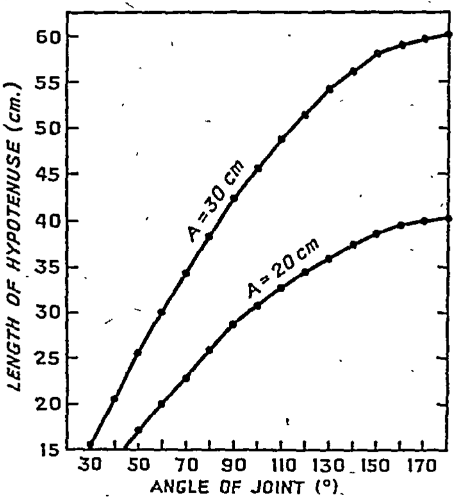

Fig. 2—Relation between hypotenuse and angle of movement of a joint.

This method of measurement can be applied to the joints and movements shown in table I.

For the purpose of comparison of one patient with another it is necessary to measure equal distances from the joint along both the arms of the angle they contain. If bony points were taken, a separate graph would have to be constructed for each patient.

In assessing the progress of a patient it is unnecessary to convert the hypotenuse to the angle, because the distances will show how much improvement has taken place.

An attempt has been made to compare this method with the method of angle measurement. It is almost impossible to do this accurately, because the difficulties of measuring the included angle are insuperable. If, however, ink lines are drawn along arm and forearm from the axis of the elbow-joint and the angle contained by these lines is measured, very close correspondence is found between this angle and that obtained from fig. 2 by measuring the hypotenuse.

TABLE II—COMPARISON OF METHODS

Observer	Case 1			Case 2		
	Angle by protractor	Hypotenuse	Angle from hypot.	Angle by protractor	Hypotenuse	Angle from hypot.
A	118	32·5	108	125	37·5	140
B	104	32·5	108	136	38	145
C	123	32·8	110	136	38	145
D	115	32·5	108	140	38	145
E	115	32·4	107	127	37	135

Comparison of the error of the two methods has been made as follows: Five observers were independently asked to measure the angle and the hypotenuse opposite the angle of two fixed joints. An elbow was chosen in each case, and the results were as follows: a variation range of (1) 104–123°, (2) 125–140° by the protractor method and of (1) 107–110°, (2) 135–145° by the method described above. The variations between the observers are shown in table II.

It is clear from fig. 2 that by the method described small angles are measured much more accurately than angles greater than 140°. Accordingly, improvement in flexion is more accurately measured than improvement in extension.

I have to thank Dr. Ernest Fletcher, physician in charge of the department, for advice and encouragement and for access to patients.

Medical Societies

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

Daraprim in Malaria

At a meeting of this society held on July 17 with Sir Neil Hamilton Fairley, F.R.S., the president, in the chair, papers were presented on the new antimalarial drug, 'Daraprim.'

Dr. G. H. Hitchings (New York) opened with a discussion of the biochemical properties of the diaminopyrimidines. These drugs are competitive antagonists of the folic-folinic acid system in the growth of *Lactobacillus casei.* A formal structural analogy between members of the series and proguanil, and certain similarities of microbiological behaviour, led to the trial of the compounds as antimalarials. A comprehensive series of some 300 diaminopyrimidines, having different substituents in the 5- and 6- positions, were studied, and from among these daraprim (2 : 4-diamino-5-*p*-chlorophenyl-6-ethylpyrimidine) was selected for clinical trial because of its high activity against several species of malaria parasites in laboratory animals.

Experiments were described which suggested that the antimalarial action of daraprim is probably associated with its activity as an anti-metabolite of the folic-acid series of vitamins and that the drug may be regarded as a structural analogue of folinic acid of a rather remote sort, particularly well adapted to displacement of the metabolite from its apoenzyme in the malaria parasite.

Mr. I. M. Rollo described the methods used for testing the antimalarial activity of these compounds against *Plasmodium gallinaceum* in chicks and *P. berghei* in mice, and traced the steps by which daraprim was selected. He mentioned resistance as a potential limiting factor of the usefulness of the drug and said that, by a specially adjusted system of dosage, he had produced daraprim-resistant strains of *P. gallinaceum* and *P. berghei.* He had found that a strain of *P. gallinaceum* resistant to proguanil was only slightly resistant to daraprim, but the position of cross-resistance in general was still somewhat confused.

Dr. L. G. Goodwin gave a review of clinical trials and pharmacology. The first results came from Lagos, where it was found that single doses of as little as 5 mg. of daraprim cleared the asexual parasites of *P. falciparum* from the peripheral circulation of symptom-free "carriers" (school-children) for about a month. From Gambia, Tunisia, India, and Indo-China results in the treatment of overt attacks of malignant, benign tertian, and quartan malaria were favourable. A single dose, usually of 50 mg., served to bring about clinical cure in most premunised subjects, though the rate of disappearance of parasites and fever was occasionally slow. Gametocytes of *P. falciparum* appeared to be unaffected, but in fact failed to develop when ingested by the mosquito. In Malaya results were less satisfactory and a number of failures had been recorded. In the Belgian Congo, an experiment in mass suppression gave very favourable results.

Daraprim, when given in large doses, produces symptoms which are probably associated with a deficiency of the folic-folinic acid series of vitamins. As the recommended therapeutic and suppressive dose is less than a hundredth of the amount required to produce such symptoms in the monkey, the question of toxicity in man does not arise. Relatively high doses have been taken by volunteers over varying periods without ill effect.

A report from Dr. G. Robert Coatney of the National Institutes of Health, Bethesda, Maryland, was read. He found that a weekly dose of 25 mg. of daraprim, given to volunteers infected on one occasion only by mosquito-bite with the Chesson strain of *P. vivax,* completely suppressed the infection; no relapses occurred up to 251 days after cessation of treatment. With repeated infections, two out of the three volunteers relapsed some time after withdrawal of the drug. With weekly doses of 12·5 mg. or less, relapses occurred when medication ceased, but even 0·78 mg. once weekly caused complete suppression while the drug was being taken. A weekly dose of 0·39 mg. did not give complete suppression; transient fever and parasitæmia were observed but there were no frank attacks. Once-weekly doses of 300 mg. of proguanil or of chloroquine in parallel experiments suppressed the infection, but relapses occurred on withdrawal. Dr. Coatney also had some evidence of true causal prophylactic action. Treatment of early malarial attacks with a single dose of 25 mg. of daraprim reduced the fever almost as quickly as 600 mg. of chloroquine, although parasitæmia persisted longer after daraprim. A tolerance test in twelve volunteers showed that, during treatment with 25 mg. daily for seven weeks, a fall in red blood-cells occurred in one of them, and Dr. Coatney thinks that this dosage may exceed the limit of tolerance for some individuals.

Dr. C. L. Oakley showed slides of the lesions in bone-marrow, spleen, adrenal, and kidney, produced in monkeys by repeated high doses of daraprim, and expressed the opinion that they arose from arrested maturation of the cells and could be attributed to folic-folinic acid deficiency. He was satisfied that, with the possible exception of metaplasia of the epithelium of the kidney and bladder, the changes were reversible. He emphasised that these toxic results occurred irregularly and with doses vastly in excess of those used for therapy or suppression. Other speakers in the discussion which followed recorded observations in general agreement with these conclusions.

Dr. Dean Smith described successful trials in Gambia, where daraprim had been used both therapeutically and for mass suppression. It had also been given in weekly doses to infants from birth onwards with good results. For this particular purpose, and indeed for all mass suppression, the fact that the drug was tasteless was of considerable importance.

Dr. Thomas Wilson (Kuala Lumpur) discussed the findings in Malaya, where in several cases daraprim had failed to effect cure. Similar results were being obtained with proguanil, but this did not appear to be due to cross-resistance. He did not regard daraprim as a suitable drug for use against the Malayan strain of *P. falciparum.*

Sir George McRobert told of six cases of relapsing *vivax* infection from Korea which had been treated in the Tropical Diseases Hospital. In these the parasitæmia had persisted for a number of days. On the other hand, Mr. P. G. Shute (Epsom) had found that a single dose of 25 mg. produced apparent cure in a patient infected with *P. vivax* for therapeutic purposes. The patient had subsequently to be reinfected.

The President, referring to these discrepancies, drew attention to the well-known but oft-forgotten fact that different races of the malaria parasite vary greatly in their response to different drugs. He saw a strong similarity between the action of daraprim and proguanil and expressed the opinion that in the cases of *vivax* infection he had seen in the Tropical Diseases Hospital subinoculations after perhaps the third day would have failed to produce infection despite the presence of parasites in the blood. Though he was unable to explain the failures in Dr. Coatney's multiple-infection experiment he considered his results of great interest, and thought it possible that daraprim might have specific activity against the late tissue forms of *P. vivax.*

He thought that neither daraprim nor proguanil were altogether suitable for the treatment of overt malaria, and that their most important rôle was as suppressants.

New Inventions

A ONE-WAY VALVE FOR MULTIPLE INJECTIONS FROM ONE SYRINGE

THE danger of using one syringe to give multiple injections is well known. Hughes[1] and Evans and Spooner[2] have shown that contamination of the syringe may be due to the negative pressure induced in the syringe when the needle is detached. The presence of this negative pressure is easily shown by the fact that a drop of fluid hanging from the point of the needle is sucked in at the moment of removal. Reflux of fluid to the syringe at some stage of the injection—e.g., during the withdrawal of the needle from the skin—is another cause of contamination, which can be shown by injections into fluids under a known pressure (" artificial mouse ").

Up to now the only safe method of preventing such contamination has been the sterilisation of needle and syringe after each inoculation. Changing the needle after each inoculation, according to the recommendations of the Medical Research Council seven years ago,[3] appears to be a sure method of transferring infection. The advice of Fleming and Ogilvie[4] to dip the needle, without detaching it from the syringe, in a hot oil bath (liquid paraffin at 130°C) for 10 seconds, applies only to contamination of the needle and not to that of the syringe.

But, as is shown in the following experiment, even the needle cannot be sterilised in this way, if it has been contaminated with a virus beforehand.

A sterile syringe was filled with sterile broth. The needle (size 12) was infected by dipping half the shaft in a 5% emulsion of a vaccinia egg-culture. The infected part or more of the needle was dipped in a hot oil bath (130°C) for 10 seconds. Then one drop of the broth was pressed through the needle and inoculated on to the chorio-allantoic membrane of each of four duck's eggs. All of them showed vaccinia infection after 3 days. The experiment was repeated on three occasions; on each occasion vaccinia infection of the membrane resulted.

The only way to avoid the necessity of sterilising both needle and syringe after each injection is to prevent reflux of fluid on to the nozzle of the syringe *in all circumstances*, so that the nozzle and the syringe contents are protected from contamination. A simple device which achieves this object is described here.*

THE APPARATUS

A one-way valve between the needle and the syringe allows the fluid to pass only from syringe to needle.

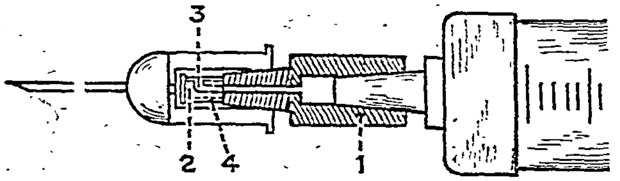

Fig. 1—Construction of one-way valve: 1, brass tube; 2, tapered end; 3, aperture; 4, rubber collar.

The valve (see figs. 1 and 2) is a tapering nickel-plated brass tube, with two lateral apertures closed by a rubber collar. The fluid forced by the piston from the syringe through the tube passes through the lateral openings, displacing the rubber collar, into the needle. Back pressure from the needle to the syringe merely closes the valve, preventing reflux of fluid and protecting the syringe against contamination. After every inoculation the needle and valve must be changed, but there is no need to sterilise the syringe.

EXPERIMENTS ON ANIMALS

The efficacy of the valve is easily demonstrated in the laboratory by the mouse-inoculation method.

Mice were infected intraperitoneally with a highly virulent strain of streptococcus (Aronson), which in very small doses kills mice within twenty-four hours. After eighteen hours an infected dead mouse was injected intraperitoneally with 0·5 ml. of sterile broth from a 'Record' syringe containing 2 ml. The needle was left in the abdominal cavity for ten seconds; it was then withdrawn, care being taken not to move the plunger. Another sterile needle was then substituted for the first, and 0·25 ml. of broth from the same syringe was injected intraperitoneally into a normal mouse. Three separate series of such experiments were made, using 5, 6, and 10 normal mice. All the mice died within twenty-four hours (see table).

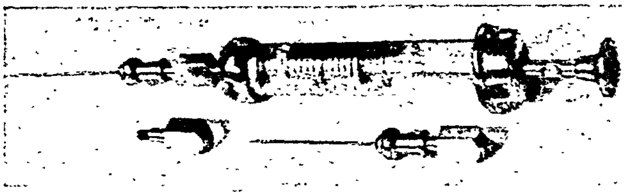

Fig. 2—The valve, the valve fitted to the needle, and the valve and needle fitted to the syringe.

Simultaneously, three similar series of experiments were made with the needle and one-way valve described above, no care being taken to avoid movement of the plunger during withdrawal of the needle from the abdominal cavity of the infected mice; the set was changed after each injection into an infected mouse; and series of 9, 8, and 8 normal mice were treated. *None of these 25 mice showed symptoms* of infection during the observation period of two weeks (see table).

NORMAL MICE INJECTED INTRAPERITONEALLY WITH 0·25 ML. BROTH FROM A SYRINGE PREVIOUSLY USED FOR THE INJECTION OF 0·5 ML. BROTH INTO THE PERITONEAL CAVITY OF A MOUSE THAT HAD DIED FROM STREPTOCOCCAL INFECTION

Test	Without valve. Changing the needle between the inoculations into the infected and normal mouse		With valve. Changing the valve-needle set between the inoculations into the infected and normal mouse	
	No. of mice inoculated	No. of deaths within 24 hours	No. of mice inoculated	No. of deaths or diseased mice
I	5	5	9	0
II	6	6	8	0
III	10	10	8	0
Total	21	21	25	0

These experiments show that the valve affords full protection against transmission of streptococci. Since this effect does not depend on the properties of the infecting agent, similar protection can be expected against transmission of any virus. The valve is now being used at our institute for the purpose of preventing serum-hepatitis arising from mass inoculations.

DIRECTIONS FOR USE

The one-way valve should be used when a single sterile syringe has to serve for multiple injections without being sterilised between injections. The valve cannot be used for withdrawing fluids. The working of the valve is tested by feeling resistance when the plunger is pulled. (It has to be remembered, however, that old syringes may be leaky, leading to underestimation of the tightness of the valve.) The injection is given in the usual way. The rubber collar offers some resistance to the fluid, but this can easily be overcome. It is essential that the valve-needle set should fit the nozzle of the syringe firmly so that it is not blown off. In giving intravenous injections, to check the position of the needle in the vein, the syringe and valve together can be disconnected from the needle to allow the blood to

flow out for a moment. After each injection the valve and needle must be exchanged for a fresh sterile set.

Cleaning and Sterilisation

A little water is syringed through the valve to remove remnants of injection fluid. The valves can be sterilised by boiling or by autoclaving. In the latter instance it is convenient to assemble the needles and valves before sterilisation. Disinfection in alcohol is unreliable and damages the rubber collar.

Testing Valves

The valve is fitted to a needle and syringe. The needle is dipped in water, and the plunger is pulled for ten seconds; no water should enter the syringe. The test is best done with a tuberculin syringe (1 ml.) immediately before sterilising valves and needles.

Repair

The rubber collar withstands numerous injections and sterilisations. Condemned valves can be repaired by renewing the rubber collar.

Reviews of Books

Commentary on Age

KENNETH WALKER, F.R.C.S. London: Jonathan Cape. 1952. Pp. 192. 12*s*. 6*d*.

Mr. Walker has found "old age to be far less disconcerting at close quarters than it appeared at a distance"; and that is, in brief, the lesson he tries to teach. (He admits, however, that he is really only now approaching the fringes of old age.) It is slowly being realised that many unpleasant things once thought to be the necessary concomitants of old age can be prevented—not by a regimen, in youth, of deadening austerity, but by an awareness that changes will become necessary, and that the transition from middle to old age can be painless.

Mr. Walker gives a clear account of the ageing process, both anatomically and physiologically, and follows this by a sensible summing up of the various controversies on rejuvenation. He emphasises how important is the psychological aspect of any rejuvenation operation, but warns that "ageing is a highly complex process and if it is ever to be arrested or reversed it will be by means of remedies so difficult to apply that our patients may well prefer to keep to the customary road and to grow old in accordance with the dictates of Nature." But the prospect is not all pleasing: the waning of the influence of the Church has left a void in many a person's emotional life, and unless that can be filled "the last stages of the journey through life become a journey of weariness and despair." On the whole, however, this is a useful and encouraging book by one who has developed a realistic and helpful philosophy.

Understanding Natural Childbirth

HERBERT J. THOMS, M.D., in collaboration with LAURENCE G. ROTH, M.D.; Picture Story by DAVID LINTON. New York and London: Staples Press. 1952. Pp. 112. 17*s*. 6*d*.

THIS book is designed to prepare the pregnant mother for the bodily changes of pregnancy and to help her to coöperate fully during her labour and delivery. There have been books similar in aim, of the "natural childbirth" school, but they have lacked the dramatic serial photographs of the process by David Linton, some of which were published in *Time* and *Life* and *Picture Post* while others are seen here for the first time. These are very well done, presenting beautifully the familiar emotional landmarks of labour. Some previous books in this category have been either over-emotional or over-technical. This one presents complex facts in a simple and detached manner, the message of each section being summed up in chapter headings quoted from such English authorities as Prof. W. C. W. Nixon, Dr. Grantly Dick Read, Dr. Janet Vaughan, and the late Mrs. Helen Heardman, as well as from American sources. The text shows well how a maternity hospital can be run on a basis of mutual understanding between all its participants, and reminds readers that if the father is allowed to help, a woman need never be left alone during labour; that the baby who is put to the breast immediately after birth acquires the sucking habit easily, giving the mother confidence in suckling, and aiding involution; and finally that group discussion is a good way to allay fear.

Urine and the Urinary Sediment

A practical manual and atlas. RICHARD W. LIPPMAN, M.D., research associate, Institute for Medical Research, Cedars of Lebanon Hospital, Los Angeles. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 124. 55*s*.

A COLLEAGUE of the late Dr. Thomas Addis, Dr. Lippman has long been a keen and careful observer of the urinary sediment in disease; and the main feature of his book is a series of beautiful colour photographs of casts, cells, and crystals, as they occur in the urine in various diseases. These pictures are splendid and the methods and findings well described. Here, perhaps, is the last word on the urinary sediment. The price is high, but many hospital laboratories will want to possess this book, both as a work of reference and for the instruction of medical students and technicians.

Biological Antioxidants

Transactions of the Fifth Conference Nov. 30–Dec. 1, 1950. Editor: COSMO G. MACKENZIE, department of biochemistry, University of Colorado. New York: Josiah Macy, Jr., Foundation. 1952. Pp. 229. $3.75.

THE discussions at this conference were primarily about the chemical effects, particularly the oxidative effects, of radiation on biological systems—from that of the whole mouse (A. M. Brues) to that of the humblest bacterium (O. Wyss).

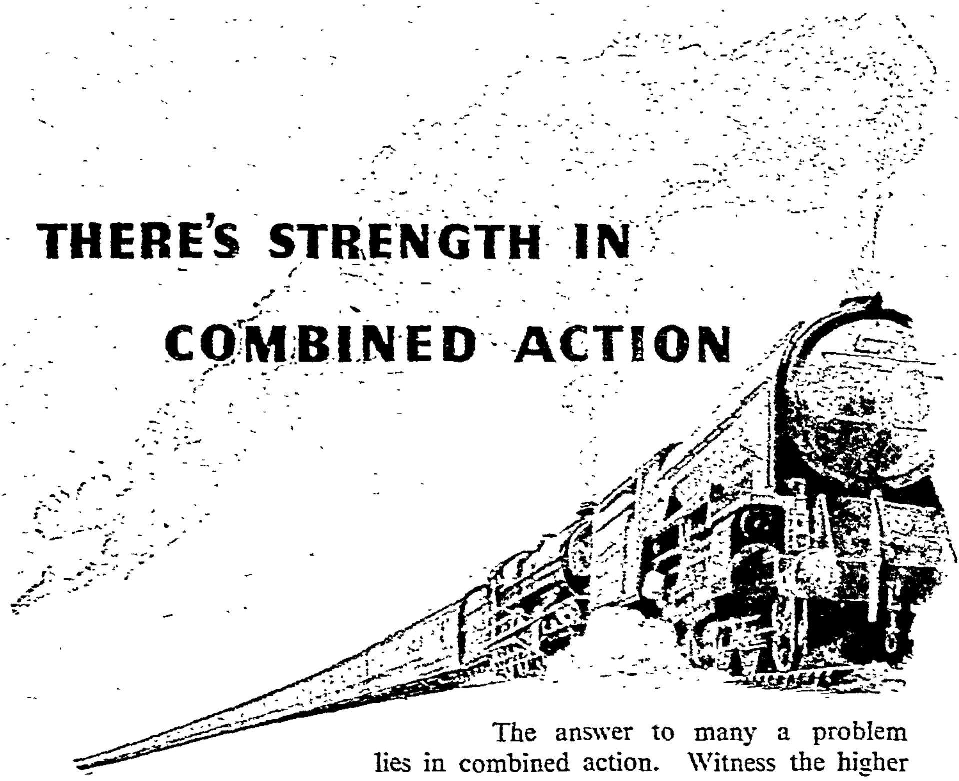
Discussions on the physicochemical effects of radiation on solutions in vitro (R. S. Livingston), and the effects of sulphydral systems, chiefly enzymes, also in vitro (E. S. Guzman Barron) are reported fully. These communications deal primarily with oxidation and to a much smaller and more variable extent with antioxidants; however, Free Radicals, Peroxides, and Antioxidants in Some Biological Processes, by E. V. Jensen, is packed with good meat on antioxidants.

While the report will be of interest to radiobiologists and others with previous experience in the field, it is doubtful if it will be intelligible to the newcomer or the general reader. The proceedings have been reported verbatim and interjections seem to have been encouraged. Many of these result in remote deviations from the theme, so that continuity of argument is lost. If the tea-table conversation of a rather large and progressive laboratory were reported it would perhaps read like this report.

Essentials of Anæsthesia (5th ed. Oxford: Blackwell Scientific Publications. 1952. Pp. 378. 40*s*.).—The fifth edition of this useful general work by Prof. R. R. Macintosh and Dr. Freda Bannister includes a chapter on curare and other muscle relaxants introduced during the last few years. The impact of these drugs on anæsthesia has, indeed, made additions and modifications necessary throughout the book, but otherwise it is much the same. Dr. Bannister has been entirely responsible for the latest revision.

Clark's Applied Pharmacology (8th ed. London: J. & A. Churchill. 1952. Pp. 691. 37*s*. 6*d*.).—For a long time to come the doctor's knowledge of pharmacology is likely to be composite—derived in part from experimental work in the pharmacological and physiological laboratories, in part from the mass of empirical therapeutics which he learned as a student in the wards, and in part from the announcements of the manufacturing pharmacists. The textbook which deals adequately with both experimental and empirical pharmacology has still to be written, but "Clark" has always been deservedly popular with senior students and practitioners because it shows some awareness of the pharmacological problems of medical practice. In their revision Prof. Andrew Wilson and Dr. H. O. Schild have maintained this tradition, but their wish to be comprehensive has involved compensatory sacrifices, and some sections of the book seem unnecessarily meagre—to physiologist and clinician alike. They are to be congratulated on bringing the text up to date without impairing the structure of the original, but there are perhaps more misprints and minor errors than there should be. Some of the lighter touches are of a kind which will not be well received by all readers, and the need for plain words is apparent here and there.

THERE'S STRENGTH IN COMBINED ACTION



The answer to many a problem lies in combined action. Witness the higher blood levels and the greater clinical efficacy that have been reported from the oral administration of penicillin and the sulphonamides simultaneously in cases when the oral administration of the antibiotic or chemotherapeutic agent alone has been ineffective. A convenient means of applying this combined antibacterial therapy is Sulpenin. Containing penicillin, sulphadiazine and sulphamerazine in balanced dosage, it provides a valuable treatment for many infections due to susceptible micro-organisms. By utilising the synergistic action between penicillin and the sulphonamides the antibacterial range is increased, the likelihood of kidney damage is lessened and the tendency for the bacteria to develop mutant strains resistant to one or other of the component drugs is reduced.

ALLEN & HANBURYS LTD · LONDON · E·2
TELEPHONE: BISHOPSGATE 3201 (20 LINES). TELEGRAMS: "GREENBURYS, BETH, LONDON"

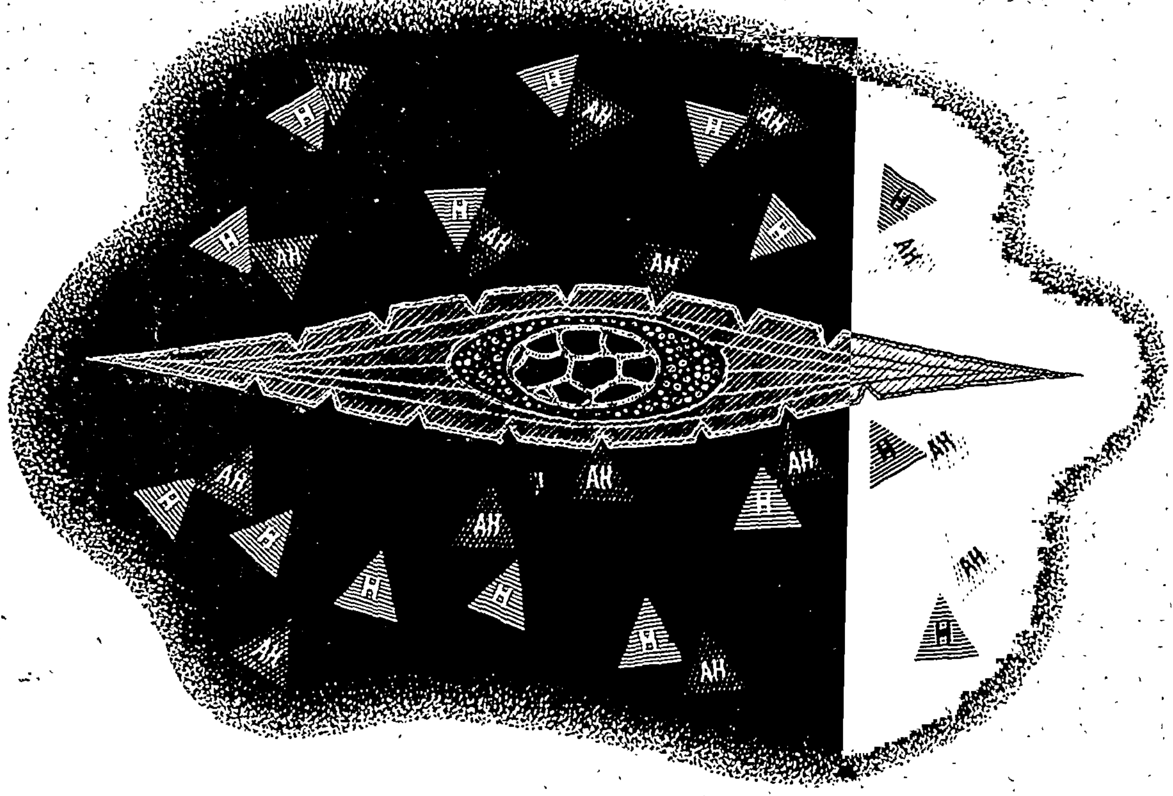

Diagram symbolizing competition for "shock-tissue" receptor sites by histamine (H) and an antihistaminic (AH).

Modus operandi....

The clinical use of antihistaminics such as mepyramine maleate and promethazine hydrochloride for the symptomatic relief of allergic and anaphylactic conditions is based on the theory of histamine-release.

According to this concept, allergy is the result of a reaction between the sensitizing substance, the allergen or antigen, and specific antibodies produced by the body. Once the hypersensitive individual has become sensitized, further exposure to the offending substance results in excess release of histamine or a histamine-like compound, which in turn provokes the allergic manifestation. The nature of this response in a particular individual depends on the part or parts of the body acting as "shock-tissues".

The antihistaminics are not believed to prevent the antigen-antibody reaction in the "shock-tissue", nor to destroy the histamine thereby released, but it is thought that in some unknown manner, perhaps by competing for and occupying or blocking the receptor-sites in the "shock-tissues", they prevent tissue damage by histamine.

SUPPLIES

'ANTHISAN'

trade mark brand

MEPYRAMINE MALEATE

the general purpose antihistaminic.

Tablets	Containers of 25, 100 and 500 x 0·05 and 0·10 Gm.
Elixir	Bottles of 4 and 40 fl. oz.
2·5% solution	Boxes of 10 x 2 c.c. ampoules
2·0% cream	Containers of 1 oz. and 1 lb.

'PHENERGAN'

trade mark brand

PROMETHAZINE HYDROCHLORIDE

the antihistaminic combining powerful and prolonged activity with subsidiary pharmacological properties useful in certain cases.

Tablets	Containers of 25 and 500 x 0·01 and 0·025 Gm.
Elixir	Bottles of 4 and 40 fl. oz.
2·5% solution	Boxes of 10 x 2 c.c. ampoules
2·0% cream	Containers of 1 oz. and 1 lb.

Detailed literature will gladly be sent on request.

Rational Use of Antibiotics

THE need is great, though the time is not ripe, for a simple guide to the intelligent use of antimicrobial drugs. The ordinary doctor is bewildered by the complexities of chemotherapy. On the one hand the number of drugs steadily increases, while on the other the sensitivity of bacteria to these drugs seems steadily to decrease, and there are dangers of sensitisation and of "superinfection" with endogenous drug-resistant bacteria and fungi.

There is probably much sense in the old adage "use the new drug while it still acts"; for the microbial reaction to attack by the new antibiotics is to develop variants which resist one or more of these agents. Because of this and the evidence that a combination of two drugs may be more effective than each separately, and may inhibit the emergence of resistant bacterial strains, combined chemotherapy is becoming more usual. The outstanding example is the combination of streptomycin and P.A.S., which in pulmonary tuberculosis is therapeutically better than either drug alone and is most effective in preventing the development of streptomycin-resistant tubercle bacilli.[1] However, one swallow does not make a summer; and "shot-gun" therapy has its risks. The recent studies of JAWETZ and his colleagues[2] illustrate the possible dangers of certain combinations of antibiotics. JAWETZ[3] has suggested certain rules for the rational use of existing antimicrobial agents. These he divides into two broad groups: (*a*) group 1, which contains the bactericidal drugs such as penicillin, streptomycin, and bacitracin; and (*b*) group 2, which consists of drugs that are mainly bacteriostatic (e.g., aureomycin, chloramphenicol, terramycin, and possibly the sulphonamides). Pairs of drugs from either group or from both groups may have an increased activity, either additive or synergistic; or they may have a decreased or antagonistic activity; or they may simply have the activity of one or other of the drugs alone. With an additive action a half dose of each of two drugs has the same effect as a full dose of one or the other; this has little to recommend it unless it is indicated on pharmacological grounds to reduce toxicity or promote absorption. A synergistic effect implies an increased bactericidal action and a rate of cure beyond that obtained additively; while antagonism has the opposite implication. The agents in JAWETZ's group 1 when used in combination, either in the test-tube or in experimental infections, are commonly synergistic, occasionally indifferent, but never antagonistic. The synergistic action is corroborated by clinical experience, as when penicillin plus streptomycin cures subacute bacterial endocarditis which has resisted penicillin or streptomycin alone. Members of group 2 are neither synergistic nor antagonistic when used together, but simple additive effects are usual. Thus, there is little to be gained by combining small doses of aureomycin and chloramphenicol when an adequate dose of one or other would be effective. Incidentally, the optimum dose of these new drugs may be less than was originally suggested; for example, in the U.S.A. aureomycin is now being given in doses of 0·25 g., instead of 0·5 g., three or four times daily.

Difficulties arise when a bactericidal drug is used in combination with a bacteriostatic drug. If the organism is sensitive to the bactericidal agent, then the addition of a bacteriostatic drug is likely to have an antagonistic action. If, on the other hand, the organism is resistant to the bactericidal drug but can be inhibited by a large dose, then a combination of the two drugs may have a synergistic effect. Thus, if a combination of penicillin and chloramphenicol is used against a penicillin-sensitive streptococcus the anti-streptococcal activity may be reduced; but if this combination is used against a penicillin-resistant proteus bacillus a synergistic action may be expected. This reversal of combined activity from the use of a bactericidal and a bacteriostatic drug may be seen also in resistant mutants of organisms, such as the staphylococcus, that are ordinarily susceptible to the group-1 drugs. To what extent these findings are applicable to clinical practice is not yet known; in experimental infections dosage has to be carefully adjusted in order to demonstrate the antagonistic action of two drugs, and indeed contradictory findings have been reported.[4] There is, however, some clinical support for the laboratory findings, as in the disappointing results from the combined use of penicillin and aureomycin in pneumococcal meningitis.[5] It would therefore seem reasonable to avoid combinations of bactericidal and bacteriostatic drugs unless there are good clinical reasons for such a combination.

Another difficulty—and this is particularly evident in hospital practice—is the ever-increasing incidence of drug-resistant variants of the common pathogens. Penicillin-resistant staphylococci are now well established in most hospitals, and there are reports of an increasing incidence of streptomycin-resistant staphylococci and a high proportion of streptomycin-resistant gram-negative bacilli, including proteus and pyocyaneus. Interest in this regard is now focused on the newer antibiotics. While there is little evidence in this country that the pathogenic staphylococci are naturally resistant to these new antibiotics,[6]

resistance can be induced fairly readily in the test-tube and there are reports from this[7] and other countries of resistant strains in clinical practice. Thomson[7A] and his colleagues in Australia have found an increasing incidence of resistant coliform organisms as well as of staphylococci in hospital, where cross-infection undoubtedly plays a part. Cross-resistance between aureomycin and terramycin, which are closely related, is common; but resistance between these two substances and chloramphenicol is more irregular. Strangely enough, increased resistance to this group of drugs may be accompanied by enhanced sensitivity to streptomycin or penicillin.

The latest observations on the synergistic and antagonistic activities of drugs and the development of resistance[8] and cross-resistance should stimulate further study of their mode of action on bacteria, about which we still know remarkably little. Meanwhile, what has already been learnt should serve as a deterrent to the indiscriminate use of these drugs; for they are not only very expensive but have a selective action against infections, most of which terminated satisfactorily in the pre-antibiotic era.

Intracranial Thrombophlebitis

In the past twenty years thrombosis of cerebral veins and of the dural sinuses, particularly the superior longitudinal sinus, has been increasingly recognised as a cause of sudden episodes of focal neurological disturbance and raised intracranial pressure.

In 1912 Passot[9] described a syndrome which occasionally followed otitis media and was characterised by headache, drowsiness, and papillœdema without pyrexia or signs of meningeal irritation; the pressure of the cerebrospinal fluid was raised but its constituents were normal. The condition was not, however, generally recognised until 1931 when Symonds[10] described again the clinical features, emphasised that the prognosis was good, and named the disorder otitic hydrocephalus. A few years later he suggested[11] that the cause of the raised intracranial pressure was thrombosis of the superior longitudinal sinus, basing this view on the presence of thrombosis of the lateral sinus on the side of the affected ear in a high proportion of the cases in which the mastoid was explored, and on the necropsy findings in a case described by Bailey and Hass[12] in which thrombosis of the lateral sinus had spread to the superior longitudinal sinus with resulting papillœdema and raised intracranial pressure. This view of the pathology of otitic hydrocephalus is now generally accepted. The raised intracranial pressure with thrombosis of the superior longitudinal sinus may be due to either of two mechanisms. The clot may spread from one lateral sinus to the torcula and in this way shut off the opposite lateral sinus and obstruct the main venous return from the cranial cavity, with subsequent œdema of the brain; or, alternatively, clot in the superior longitudinal sinus may block the arachnoid villi and in this way impede the absorption of cerebrospinal fluid. Ventriculography has shown that in the great majority of patients with otitic hydrocephalus the ventricles are of normal size, the hydrocephalus being a communicating one with an equal rise of cerebrospinal-fluid pressure inside and outside the brain. The prognosis in these cases is almost uniformly good; the papillœdema and raised intracranial pressure gradually subside, owing to recanalisation of the thrombus. Occasionally, however, optic atrophy with failure of vision takes place before the natural recession of the papillœdema. The usual treatment is repeated lumbar puncture to reduce the intracranial pressure; commonly the pressure falls after two or three punctures, but in some cases puncture may have to be repeated for several weeks. In general this treatment is safe, but Symonds[13] has recently described a patient with otitic hydrocephalus who died shortly after lumbar puncture. Probably this was a result of cerebral œdema with tentorial herniation due to withdrawal of cerebrospinal fluid; and he advises that the fluid should be withdrawn slowly and the pressure not be allowed to fall below 150 mm. water.

Another complication of otitis media, which may arise in association with otitic hydrocephalus or apart from it, is Gradenigo's syndrome, in which a sixth-nerve palsy develops on the side of the infected ear. This condition is probably also due to thrombosis of a sinus—the inferior petrosal sinus.[13] This sinus and the sixth nerve pass from the posterior to the middle fossa through a tightly fitting dural sheath—Dorello's canal—and the palsy results from compression of the nerve by the thrombosed sinus, the nerve recovering its function as the sinus becomes recanalised.

Thrombophlebitis of superficial cerebral veins may occur in association with infection in the ear or nasal sinuses or with localised or generalised infections elsewhere in the body[14,15]; and here the usual clinical picture is of focal epileptic attacks followed by loss of function of the parts of the body involved in the attack. More rarely hemiplegia or aphasia may develop suddenly without preceding epilepsy. Often there are general symptoms of infection, and the cerebrospinal fluid may show a cellular reaction, unlike the state with sinus thrombosis where the fluid is usually normal. The diagnosis from a cerebral abscess may be difficult, and indeed an abscess may occasionally follow cerebral thrombophlebitis. With the administration of antibiotics, however, the majority of patients make a good recovery, though there may be residual hemiparesis or hemianopia, depending on the part of the brain involved and the extent of brain damage.

Intracranial thrombophlebitis also occasionally comes on during the puerperium[16]; and possibly the sudden cerebral vascular catastrophes after childbirth described by Ménière[17] in 1828 were of this nature. Martin[18] has suggested that in these puerperal cases the starting-point may be thrombosis in a pelvic vein, and that a detached fragment of clot may pass as an embolus up the extrathecal vertebral plexus of veins, which is largely without valves and communicates with the intracranial venous sinuses. Kendall,[15] on the

other hand, has pointed out that in the puerperium some factors favour "primary" thrombosis. There is an increase of blood-platelets,[19] especially if there has been severe postpartum hæmorrhage; the plasma-fibrinogen is raised [20]; and there is increased "stickiness" of the circulating blood,[21] possibly owing to an increased number of newly formed cells. These factors would all enhance the tendency to thrombosis in the presence of damage to the endothelium of intracranial veins or sinuses, which might occur during labour. In this connection it is interesting that thrombosis of intracranial venous sinuses has been reported following combined insulin-induced hypoglycæmia and electric convulsive therapy [22] in the treatment of schizophrenia. The suggestion was that the endothelium was damaged during the fits, and thrombosis was precipitated by the dehydration from sweating and salivation during hypoglycæmia.

Stillbirth and Social Conditions

PROGRESS, like growth, is a thing of fits and starts—and stops; and no better illustration of this can be found than the behaviour of the stillbirth-rate in recent years. Whereas during the nine years 1931–39 the rate scarcely declined, falling from 41 to 38 (7%), in the next nine years 1939–47 it fell from 38 to 24 (37%). This change was all the more remarkable because it took place mainly during the years of war and because it has not continued during the years of relative peace; in the last four years, 1948–51, the stillbirth-rate has remained constant at 23.

There are two ways of looking at these changes. On the one hand it may be said that what has happened is no more than was to be expected. The improvement in the technical quality of the maternity service consequent on the better control of sepsis, the use of antibiotics, and the improved facilities for blood-transfusion was bound to reduce the number of stillbirths just as it lowered maternal mortality [23]; and delay of a few years between cause and full effect need not surprise us. Though the beneficial effect of the antibiotics, &c., were soon apparent, obstetricians had to tread warily when it came to testing the many other new measures that were the logical outcome of these changes. For example, the expectant treatment of some cases of antepartum hæmorrhage, and the extended use of cæsarean section to include cases potentially or actually infected, were to become part of obstetric practice; but during the years under review these methods were still on trial, and no material decline in the number of stillbirths could have been expected until they were firmly established. Such might be some of the arguments supporting a close relation between the quality of obstetric practice and the stillbirth-rate. On the other hand, it may be argued that this is only half the picture. The stillbirth-rate of late years has failed to keep pace in its decline with the maternal-mortality rate, and there are other findings which together suggest that social conditions and change are also important and that the influence of environment on the stillbirth-rate should be examined in some detail.

It seems reasonable to suppose that those enjoying a high standard of living will show a better reproductive performance than those with a low standard of living. If this is so, may it not be that most of the decline in the number of stillbirths during the war and immediate post-war years should be ascribed to the social changes in the years in question? This period saw the virtual elimination of unemployment, with an increase in the amount of money spent on food, which, together with food rationing and the system of priorities, ensured for the expectant mother her fair and proper share. Such a hypothesis could explain the abrupt check in 1948 to the rapid decline in the stillbirth-rate. The previous year, 1947, it will be remembered, was a disastrous year of prolonged winter, severe flooding, and drought, in which dairy produce, meat, eggs and egg products, and oils and fats were all scarce.[24] The main question to be answered in regard to stillbirths may well be not so much whether social conditions are important as whether they are more or less important than those matters of a more technical or strictly obstetrical nature; and there is perhaps some urgency in seeking an answer, because the stillbirth-rate is no longer declining, and because further striking improvements in the technical quality of the obstetric service are improbable—at least such as those we have witnessed in the last fifteen years.

Stillbirths have been registered in England and Wales since the Births and Deaths Registration Act, 1926, which came into force in 1927, and in Scotland since 1939, and many trends in the national figures have been detected. For example, it is known that the stillbirth-rate is adversely affected by low social class and, broadly speaking, by advancing age after 25, by primiparity, and by increasing multiparity after the second child; it is also known [25] that the stillbirth-rate is similarly affected by decreasing height (or more particularly leg length) of the mother—a physical characteristic which in its turn is closely related to expenditure on food. Illegitimacy increases the likelihood of stillbirth, especially if the mother is under the age of 30, as also do unemployment and poorly paid work, though not overcrowding [26]; and there are striking geographical differences in the stillbirth-rate.[27] A poor environment and consequent lack of proper food and amenities can only be harmful to reproductive function, and may well be more harmful than factors more strictly obstetrical. It is not yet clear, however, at what age the woman is most vulnerable. Is it when she is a growing girl (if this be the case we have to look back many years for the explanation of recent trends), or is the environmental effect more harmful when acting during pregnancy? Whatever the answer, it is clearly important that a constant watch be kept on the diet of growing girls and adult women. As the first report of the Expert Committee on Maternity Care [28] says, "where food is in short supply the expectant and nursing mother and the child are the first groups in the community to suffer."

Annotations

PREREGISTRATION YEAR

THE appointed day for the introduction of the preregistration year of house-appointments required by the Medical Act of 1950 has been fixed as Jan. 1, 1953. The Act requires all newly qualified men to spend a time, now fixed as 12 months, in approved appointments before full registration is granted. The responsibility of approving hospitals for this purpose has been placed on the universities and other "licensing bodies" giving qualifying diplomas. On the advice of these bodies, the General Medical Council is preparing a list of hospitals and institutions in which house-appointments will qualify for full registration. It is hoped that the list will be completed and published by Sept. 30.

The basic machinery of the Act is simple. A student who qualifies after the end of this year will apply for an approved house-job in the usual way. When he has been offered a place he will notify the G.M.C., and the licensing body in whose area he is going to work will provide a certificate of acceptance which will entitle him to provisional registration. He will then spend 6 months in a medical post and 6 months in a surgical post, or, as an alternative to either of these, he may do an obstetrical appointment for 6 months. At the end of the year the licensing body will certify to the council that the applicant has been employed in the prescribed way, and that his service has been satisfactory. He will then become fully registered. The conditions of service and remuneration will be the same as those at present applying to house-officers in their first year. As the scheme gradually comes into full operation, the aim will be to restrict the approved posts to preregistrands, and only to appoint fully registered doctors in exceptional circumstances.

STAPHYLOCOCCAL ENDOCARDITIS

BACTERIAL endocarditis is usually due to streptococci, but not uncommonly the cause is a staphylococcus. Thayer[1] in 1931 found that staphylococci accounted for 8·2% of 536 cases; and Perry,[2] reviewing 1000 cases in 1936, recorded that 10·3% were due to this cause. Dowling and his colleagues[3] in the University of Illinois suggest that the proportion of cases of endocarditis due to staphylococci may have increased in recent years—possibly because patients with staphylococcal septicæmia are now kept alive with antibiotics long enough to develop endocarditis.

The staphylococcus is not always highly pathogenic; thus *Staph. albus* was the cause in 1% of the cases recorded by Thayer and by Perry. In these early studies tests for pathogenicity, such as coagulase or hæmolysin production, were not carried out; but since then workers[4–7] have recorded cases due to coagulase-negative staphylococci. The majority of such cases ran a protracted subacute course; but the case recorded by Cunliffe and Gillam[5] was a fulminating septicæmia with death in less than a month. Dowling et al. found that of 77 cases studied by themselves or reported by others 64 were due to *Staph. aureus* and 13 to *Staph. albus*; the coagulase test, done in 26 instances, was positive in 19 and negative in 7. Rather surprisingly they discovered no significant correlation between the biological characters of the organisms and the type of disease or the underlying condition of the heart. In addition to pathological conditions of the heart the predisposing causes of staphylococcal endocarditis are infection elsewhere in the body and practices likely to introduce bacteria. Dowling et al. believe that of recent years in America the injection of narcotics into a vein has become such a practice. Of 25 cases studied by them, 11 (6 in patients under thirty years of age) were heroin addicts.

The prognosis of staphylococcal endocarditis has been transformed by the introduction of antibiotics. Dowling et al. estimate that 47% of all cases treated with antibiotics recover. Where the infecting staphylococcus is sensitive to penicillin, this is the drug of choice. High dosage—5–10 million units a day—is necessary to penetrate to the site of infection. They recommend that the sensitivity of the infecting staphylococcus to penicillin should be estimated and the dose adjusted to maintain in the blood *at all times* at least four times the minimum concentration necessary by this estimate. It is noteworthy that in the striking case of streptococcal endocarditis described lately by Dr. Baker and Dr. Pilkington,[8] there was no response to heavy and sustained dosage with penicillin, streptomycin, aureomycin, and chloramphenicol; but apparently complete cure resulted from the very high blood-penicillin levels achieved with the aid of 'Benemid.' If improvement does not take place within five days, combination with other antibiotics (aureomycin or chloramphenicol) should be considered. For penicillin-resistant infection most workers recommend aureomycin in doses of 4–8 g. daily. In view of recent observations on chloramphenicol,[9] however, this antibiotic might be tried.

TWO HUNDRED YEARS

TWO HUNDRED YEARS ago, on Monday, July 27, the Manchester Infirmary in humble premises in Garden Street opened its charitable doors. A scrofulous youth, John Boardman by name, was the first and only patient on that day. At its second meeting the weekly board was able to record the attendance of four more outpatients and of the first inpatient, a 12-year-old lad with "sordid ulcers on the leg."

As twelve beds did not long suffice, the governors built a new infirmary on the "Daub-hole field" belonging to Sir Oswald Mosley. It was opened in the summer of 1755, but a few years later wings had been added and the handsome building was adorned by a fine blue-faced clock with large gilt letters. With a lake in front and flanked by trees, it was a haven of rest for the victims of accident and disease in a rapidly growing industrial area. But the discipline was strict, even at meetings of the governors, where it was laid down that only one person might speak at a time. Swearing by patients was prohibited, and one might not play the flute or the hautboy. In 1765 the farsighted governors built on a lunatic asylum wherein no patient could be beaten or put in the bath without order of the physician: these patients were promised "that humane treatment and that judicious advice which they had no encouragement to expect in private madhouses." The two hospitals seem to have functioned as one, for we learn that on Sunday evenings the apothecary was wont to assemble the patients and "other members of this Family" to read such practical books as might be appointed by the chaplain. After a visit of John Howard, who included infirmaries in his survey of prisons, there were improvements in the ventilation and cleanliness of the wards. Cold, warm, and vapour baths were also provided, which proved popular with the Mancunians. Prices were reasonable, including it would seem the fine of sixpence for spitting in the bath. In 1792 the enterprising physicians instituted a system of recording cancer cases "together with the collateral helps to be gained by an

enquiry into constitutional habits and disease not strictly cancerous but probably connected with it."

In telling this story Dr. William Brockbank[1] portrays the growth of the Manchester Infirmary vividly and with affection. We see its environs changing decade by decade, with gardens giving place to busy thoroughfares, but inside always the same story of Christian charity, prudence in matters of expenditure, enlightened outlook of the doctors, and a growing sense of responsibility in affairs of public health and in the teaching of medical students. In 1810 Robert Peel conveyed to the governors his Majesty's gracious approval of the Infirmary being designated " Royal." And so the hospital continued to grow and to prosper, the comfort of the sick being foremost in the minds of the governors; in 1860, for instance, engravings were purchased " depicting cheerful subjects for the purpose of conveying agreeable impressions to the minds of the sick to break the monotony of their suffering existence."

The fountains which had welcomed the young Queen Victoria were dismantled in 1866, and soon it was proposed to move the hospital to a more commodious site. The patients were eventually translated to a fine new infirmary on Dec. 1, 1908, and soon afterwards began the work of demolishing the Georgian building, which many today will recall with affection. The site where the gracious charity stood is happily now a garden, while the new medical citadel, justly proud of its heritage, claims a foremost place among our teaching hospitals.

SEROLOGICAL TESTS IN LEPROSY

It has long been known that serum from patients with leprosy is apt to give non-syphilitic reactions with various standard serum tests for syphilis (S.T.S.). Most reports on this subject have dealt with few cases; but Kvittingen et al.[2] have now investigated 821 patients with leprosy, using three serological tests—the Meinicke (M.K.I.R.), the V.D.R.L. slide-test (Venereal Disease Research Laboratory, Chamblee, Ga., U.S.A.), and the Kahn test. The sources of the sera examined covered a wide area, including Ceylon, Rangoon, Bombay, Mandi (India), Simla, Sabathu (India), and Tarataran (India). 31 sera from Mandi and Simla are omitted from this analysis because " the number of sera collected was too small for the results to be of much significance."

Unfortunately the data are not very clearly presented; but, taking the figures as a whole, it would seem that of 790 sera examined by the M.K.I.R. test, 87 (11·1%) reacted positively; of 787 sera examined by the V.D.R.L. test, 189 (24·1%) yielded positive results; while of 500 examined by the Kahn test, 169 (33·8%) were positive. From patients who were positive reactors to one or more of these tests, 62 were selected as representative of the whole group and were classified as follows: (*a*) neither history nor clinical evidence of syphilis (41); (*b*) indeterminate signs of syphilis (6); and (*c*) either history of venereal disease or clinical indications of syphilis (15). Assuming that these 62 patients were truly representative and that groups (*b*) and (*c*) were undoubtedly syphilitic, one can expect that of the positive S.T.S. reactors among patients with leprosy 66% may be non-syphilitic.

Three further points emerge from this report. Firstly, the percentage of positive S.T.S. reactors varies widely in patients with leprosy from different areas. Thus in Ceylon the M.K.I.R. test was positive in only 3·2%, whereas in Bombay this test was positive in 21%. Secondly, a cardiolipin antigen, as in the V.D.R.L. slide-test, yields a greater proportion of positive reactions than the " crude " antigen M.K.I.R. test when the same sera are tested in parallel. Thirdly, the sensitivity of two batches of V.D.R.L. antigen may vary considerably when used in parallel tests on sera. Thus with the same sera one batch of antigen yielded a positive-reaction rate of 16·9%, and another batch a positive-reaction rate of 40·2%.

THE DENTAL CONGRESS

THE 11th International Dental Congress, under the auspices of the Fédération Dentaire Internationale, is being held in London at the Royal Festival Hall from July 19 to 26. This is the first time that the congress has been held in this country; but we trust that it is not the last, for never before has there been a chance to learn so much about recent developments in dental surgery. The congress was due here in 1914 and again in 1941, but on each occasion arrangements had to be abandoned because of the outbreak of war. However, all has gone well this time, and the congress, which is the largest gathering of dental surgeons ever held in Great Britain—no less than 58 nations being represented—was opened last Saturday by the Minister of Health, Mr. Iain Macleod. The proceedings began with the induction of Dr. E. Wilfred Fish as president of the congress by Dr. Ch. F. L. Nord, president of the Féderation Dentaire. Then came the ceremonial presentation of three international dental prizes.

The scientific sessions were opened on Monday by Sir Alexander Fleming, F.R.S. The programme was so extensive that the congress had to be divided into twenty sections, and during the week over twenty international reports will have been presented and discussed. These reports, covering advances made in dentistry during the five years since the last congress, have already been published in the *International Dental Journal*, and résumés only are now being given, so that more time can be devoted to discussion. For the benefit of the many foreign delegates, simultaneous translations in the basic languages of the congress are being given over headphones attached to the seating in certain parts of the auditorium of the Festival Hall.

During the week, no less than sixty table demonstrations have been given each day, some of which were repeated over closed-circuit 1000-line television in the Tele-kinema on the South Bank. Incidentally, this is the first time that a television screen as large as 18 × 16 ft. has been used. Some twelve scientific films have been shown daily, and there has been a scientific exhibition of photographs, photomicrographs, and apparatus. A trade exhibition was also held in the hall.

In connection with the congress, a special exhibition, open to the public, is being held in the County Hall. Opened last Saturday afternoon by Miss Pat Hornsby-Smith, parliamentary secretary to the Ministry of Health, it represents an endeavour to bring home to the general public how much they themselves can do to keep their teeth healthy. The emphasis is on prevention, and the exhibits show how various countries are trying to foster public interest in preventive dentistry. The exhibit of the United States is of particular importance because it presents some of the results of the only long-term work so far done on the fluoridation of water-supplies—a matter attracting much attention in this country at the moment.[1] Two films on dental health, both specially prepared for the public, were shown for the first time on Saturday. One of them, made chiefly for children, is concerned with the training of a girl dental student and is meant to familiarise children with the appearance of dental instruments and the awe-inspiring surroundings of a dental surgery. The other presents by means of animated diagrams the structure of the teeth, and also reviews some of the problems of dental health. It is to be hoped that these films will be widely shown—especially as it appears that even in this country only one person in five owns a toothbrush, while even fewer know how to use one correctly.

[1] Mackenzie, E. F. W. *Lancet*, 1952, i, 961.

During the week most dental schools and hospitals have organised special demonstrations, and a series of lectures on recent dental research were given in the County Hall. The closing ceremony takes place in the Royal Festival Hall on July 26, and there will be a banquet for the members of the F.D.I. at the Savoy Hotel in the evening.

THE SEWAGE SWAB

IT has proved difficult in the past to isolate enteric bacilli from sewage, because the material is usually much diluted and the pathogens are greatly outnumbered by other bacteria. However, overgrowth by non-pathogens can now be largely averted with the modern highly selective culture media; and the ingenious sewage swab devised by Moore[1] has gone far to overcome the difficulty of sampling large volumes of sewage in which the pathogen is present only intermittently. Moore's method consists in lowering folded pads of gauze through the manholes into the sewers and securing them with string so that they trail in the flowing sewage. Rivers and streams may be similarly sampled. After a suitable interval—usually 48 hours—the swabs are transferred in sterile jars to the laboratory. For the isolation of paratyphoid-B bacilli, swab washings are incubated in a selenite-F enrichment medium from which platings are made next day on a deoxycholate-citrate medium containing also mannitol and lead acetate. The colonies have a characteristic appearance. Typhoid bacilli proved more troublesome to isolate, but success was eventually achieved by a combination of selenite enrichment and direct plating of successive fivefold dilutions of the swab washings on Wilson and Blair's bismuth-sulphite agar.[2]

There are now a number of records of the use of this method in tracing the source of outbreaks of enteric fever and elucidating the cause of sporadic cases. Moore[1] has described an interesting investigation in North Devon; and Lendon and MacKenzie[3] have traced infection back from a river which had been responsible for a number of cases of typhoid fever, through a storm-water overflow to the sewerage system of a residential area and ultimately to a single house, where a chronic carrier of *Salmonella typhi* was located. An essential part of these investigations is the precise typing of the isolated strains by means of Vi-bacteriophages.[4, 5] The determination of Vi antibodies in the serum of an excreter of typhoid or paratyphoid bacilli may also be of value in deciding whether the person is in fact a true chronic carrier.

Moore et al.[6] now give an account of their epidemiological findings during the field work by which Moore's technique was developed, and of a limited survey designed to give an estimate of the number of separate foci of enteric infection in a town of 10,000 people. They describe the regular isolation of paratyphoid-B bacilli from the river passing through this town, the identification of two different strains by Vi-phage typing, and the subsequent tracing back of infection—in one instance through a tributary stream—to groups of houses and sometimes (where the inhabitants coöperated) to an individual carrier. From such observations and the general survey it is inferred that there are in this town at least nine, probably distinct, foci of infection. 2 chronic paratyphoid carriers (type 2) and 1 typhoid carrier (type F1) have been located; these are the types that have been found in clinical cases in the area. The evidence suggests broadly that sporadic notific cases and the occasional epidemic may represent a outcrop from a deeper substratum of subclinical infection The key to the local problem may be the river. know to be subject to pollution with enteric bacilli, which ma reach the residents through vegetables watered from th river, or in other ways.

The report shows that enteric organisms can l regularly isolated from the sewage of communities of u to about 100 houses harbouring a single carrier; and single carrier of paratyphoid-B bacilli has been locate from the sewage of 1500–2000 people. The sewage swa method is already being used to detect poliomyelitis viru in bulked sewage, and it may also prove useful in th study of the epidemiology of bacillary dysentery an salmonella infections, and as a check on the prevalenc of intestinal infection in the staffs of establishment handling food.

VITAMIN D AND ENZYMES

IN-VITRO studies of the biochemical reactions of fa soluble substances are complicated by the difficulty o measuring their interaction with water-soluble enzym systems. Thus, though we know a great deal about th effects of vitamin D in the body, we know much less abou how these effects are brought about. Now, howeve Zetterström[1] has prepared phosphorylated vitamin D, which, being partly soluble in water, can be used fo enzyme studies. The alkaline phosphatase group o enzymes are known to be concerned with ossification and with the metabolic actions of vitamin D[3]; i rickets the alkaline phosphatase level commonly rise before symptoms or signs appear,[4] and administratio of the vitamin restores this level to normal.[5] Vitamin D also promotes the utilisation of phosphate by increasin its reabsorption in the renal tubules[6]; and Zetterströn suggests that it exerts this action through alkalin phosphatase, which it releases from bone, kidney, an intestine. These findings may help to explain the mechanism by which vitamin D prevents rickets; for it i known that for normal ossification sufficient phosphat has to be supplied to the bone-forming tissues. Zetterström[7] has also gone some way towards explaining th action of vitamin D in promoting growth generally and in impairing the oxidative phase of carbohydrat metabolism,[8, 9] by correlating the presence of the water soluble vitamin-D compounds with that of the respirator enzyme complex from the mitochondria of renal cells.

This work seems to suggest that the effects of vitamin-D deficiency may turn out to be due to associated change in enzyme function.

Dr. Catherine Chisholm, consulting physician to th Manchester Northern Hospital, and one of the founders of the Duchess of York Hospital for Babies, Manchester, died on July 21.

ON July 21 the Duke of Gloucester opened the 10th International Congress of Dermatology, which is being held in London this week under the presidency of Sir Archibald Gray.

Prof. George Macdonald, director of the Ross Institute for Tropical Medicine, London, has left England to lead a commission delegated by the World Health Organisation, to report on the medical condition of civilians in South Korea and the measures necessary for the maintenance of their health.

OBSTETRICS AND GYNÆCOLOGY

President: Prof. JOHN CUNNINGHAM

Cardiac Disease in Pregnancy

Dr. ALAN THOMPSON (Dublin) pointed out that the management of the pregnant cardiac patient did not differ greatly from that of the non-pregnant patient. He described the physiological changes in the circulation in pregnancy; these changes were the result of fluid retention, gain in weight, hydræmia, and the reduction in venous return caused by the respiratory embarrassment of the elevated diaphragm. They subjected the heart to a prolonged strain, which any complication of pregnancy could only aggravate, not to mention the hazards of labour itself. This strain was greatest at about the 32nd week, after which it lessened; this was a particularly useful time therefore for assessing the outlook for the forthcoming labour. During antenatal supervision, anæmia should be corrected, and radiological estimation of the heart-size should be made as early in pregnancy as possible while the measurement was still reliable. Auricular fibrillation was not a bar to pregnancy, provided it could be controlled by digitalis, but there was a danger of embolism. Adequate rest, admission to hospital at the first sign of failure, digitalis, fluid restriction, and mercurial diuretics formed the basis of treatment. The main risks were acute pulmonary œdema, respiratory infection, progressive failure with fibrillation, embolism, and subacute bacterial endocarditis.

Dr. ARTHUR BARRY (Dublin) thought that early diagnosis of the cardiac lesion went a long way towards ensuring safe delivery. If the lesion was missed at the first antenatal examination, it was unlikely to be found until calamity threatened. In his series of 266 cases, there was a significant history in 50%, and rheumatic heart-disease accounted for 90%, with mitral stenosis predominating. The mortality-rate was only 0·75%; no revolutionary treatment had been given, but supervision had been thorough. Cæsarean section was only used in 1·5%. The fœtal mortality of 6·6% was only slightly above the general rate. Pregnancy was only a temporary complication in the disease and, provided the immediate dangers were avoided, life was not shortened by child-bearing. There was no case either for sterilisation or for termination of pregnancy; the latter was absolutely contra-indicated as an emergency measure, and if the patient recovered from failure, it was then unnecessary. When asked if he would carry the argument to its logical conclusion and encourage rapidly repeated child-bearing, he said that future pregnancies, if necessary spent wholly in hospital, would do less damage than the tasks of looking after the other children at home. He graded his cases into the usual four groups; groups 3 and 4 were kept at absolute rest. Induction of labour was both futile and dangerous; gas-air, trilene, and ether anæsthesia were taboo because the hyperventilation they caused was harmful. Uncorrectable cardiac failure, far from calling for active obstetrical intervention, positively contra-indicated it, and when failure developed during labour, he preferred incision of the cervix and extraction of the child, using local anæsthesia with 'Hyalase,' to cæsarean section. After delivery the patient was kept in bed until her cardiac grading improved. Breast-feeding was, as far as possible, permitted in accordance with the patient's wishes.

Dr. WALTER SOMERVILLE (London) discussed valvulotomy, and he gave the criteria for deciding whether to operate during pregnancy. Mitral incompetence, other associated valvular lesions, enlargement with significant systolic expansion, and active cardiac failure were the main disqualifications. The stage of pregnancy made no difference and the operation had been performed as late as the 36th week.

Vaginal Discharge

Dr. IAN DONALD (London) dealt with the causes and investigation of this symptom, drawing his facts and figures from the Chelsea Hospital for Women. He gave some sound reasons for segregating the cases into one large clinic where investigation could be properly carried out. Sexual intercourse was a prominent cause in the large number of trichomonas infections. The ratio of pus cells to squamous cells in a fresh saline-drop preparation was a better guide to prognosis and progress than any other observation. Because relapses often followed menstruation, and because both pregnant and post-menopausal cases responded so well to treatment, he felt that menstruation was the greatest single unfavourable factor. The maximum therapeutic effort should be made during the menstrual period itself, allowing, in favourable cases, a welcome respite from treatment in between. He pointed out that careless technique in hospital can spread infection, and he condemned the slovenly practice of not changing gloves for each case. Monilia infections were more common than was generally supposed, quite apart from glycosuria and pregnancy, and spores should be looked for in the cervical canal. Considering how many patients complained of discharge but were in fact more frightened than ill, he thought that empirical treatment, given without proper assessment and diagnosis, did the patient a great psychological disservice.

Prof. WILLIAM KEARNEY (Cork) outlined the many kinds of treatment in use. He preferred antibiotics to œstrogens for vulvovaginitis in children, and in treating cervicitis he used appropriate chemotherapy after identifying the organisms responsible. Surgery was dangerous in acute cervicitis, but it was very useful in the chronic case. In treating gonorrhœa, streptomycin had the great advantage over penicillin that it did not mask concomitant syphilis.

Prematurity

Dr. J. K. FEENEY (Dublin) gave a review of cases treated at the Coombe Lying-in Hospital. Important social factors affected both the incidence of premature birth and the chances of ultimate fœtal survival. In the management of labour, the membranes should be preserved as long as possible, and episiotomy should be freely used. Forceps, applied to the aftercoming head in breech delivery, minimised the risk of intracranial hæmorrhage, particularly if they were kept in position until the head was completely born and therefore safe from sudden decompression. Anæsthesia, either local or spinal, gave the best results, especially in cæsarean section. Early clearance of the infant's air-passages by suction and gentle intubation were invaluable resuscitative measures.

Dr. MARY CROSSE (Birmingham) dealt with the physiology of the premature infant. Its greatest handicap lay in poor development of the lung alveoli, which weak respiratory muscles and an unreliable respiratory centre did nothing to help. Fœtal hæmoglobin liberated oxygen indifferently, although its affinity for oxygen was high. The presence or absence of a cough reflex really determined whether or not it was safe for a baby to be looked after at home, because of the great dangers of inhalation of mucus and regurgitated material. The control of body-temperature was all important, and it should be stabilised at 96°–97°F. Hæmorrhagic diathesis and the liability to œdema were additional risks; starvation during the first day or two was of great value in œdema, quite apart from avoiding the dangers of regurgitation. Anæmia was prevalent and might need transfusion. Unfortunately the administration of iron, though sorely needed, was useless before the child was 10 weeks old and was likely to upset digestion. Dr. Crosse showed that the rate of extrauterine growth should run parallel with what might be expected had the baby continued in its intended environment. The backwardness of the premature infant appeared exaggerated unless one, in fairness, discounted the many weeks by which its birthday was antedated in reckoning its age in comparison with full-term children. However, all such signs disappeared by the 6th year.

Dr. J. N. O'Reilly (London) outlined the management and care of the premature infant, and referred to the dangers of oxygen concentrations of over 50% which may cause retrolental fibroplasia. The climate of England, and of Ireland too, was bad enough to make fussing about humidity superfluous. Overheating was as dangerous as refrigeration, and an immediate environment of 90°F was desirable. Posture was important; propping up after feeds discouraged regurgitation, and the stomach emptied more easily if the infant was laid on its right side for a short time after feeding. Infection was a great bugbear, and septicæmia might be heralded by no more than a disinclination for food. He endorsed an initial period of starvation. Tube feeding was on the whole the best method. Hæmoglobin levels often fell to 55% but seldom beyond, and he did not advise transfusion until that level was reached. Dr. W. R. F. Collis (Dublin) disagreed with keeping the body-temperature at 96°–97°F, and he recommended giving thyroid extract to raise it.

Habitual Abortion

Dr. E. W. L. Thompson (Dublin), discussing the many causes, stressed the importance of the random factor or the chance of spontaneous cure, which was as high as 60% after a sequence of two abortions, but was only 16% after three. Any therapeutic measure had to be reviewed against this background. Rhesus iso-immunisation played no part in habitual abortion. In investigating these cases, he preferred to confine elaborate tests, over and above the routine W.R., analysis of urine, hæmoglobin estimation, and vaginal examination, to patients who had had three unsuccessful pregnancies. He then resorted to hysterography, B.M.R. and blood-cholesterol estimations, and tests of renal efficiency and pregnanediol excretion.

Dr. P. M. F. Bishop (London) referred critically to the intramuscular implantation of progesterone, which he himself had popularised. He wondered seriously whether pregnancy was not sustained by the sheer psychological force of the mumbo-jumbo which his and other impressive lines of treatment involved. This question could, of course, be put to the test by a control series of patients who were either implanted with inert substances or told that there was no help for them; but he was reluctant to carry out such an experiment, and preferred, in the absence of more definite knowledge, to stick to his own methods and their results, whatever the mechanism.

SURGERY

President: Prof. A. A. McConnell

Dysphagia

Prof. F. J. Henry (Dublin), reviewing the commonest causes of difficulty in swallowing, said that dysphagia could be classified as painful, paralytic, or obstructive. *Painful* swallowing was associated with four conditions: inflammatory lesions of the mouth and pharynx, infections of the neck, impacted foreign bodies, and peptic ulceration of the œsophagus. In the obstructive dysphagias the impediment could be extrinsic or intrinsic. In the adult, the common extrinsic obstructing lesions [illegible]nd retrosternal goitre, and enlargement [illegible] lymph-nodes by secondary malignant disease or by lymphadenopathies, such as Hodgkin's disease or leukæmia. The intrinsic obstructions were more important. The four common causes were cardiospasm, fibrous stricture of the œsophagus, a pharyngeal pouch in its later stages of development, and tumours of the pharynx, larynx, œsophagus, and cardiac end of the stomach. Professor Henry pointed out that in carcinoma, when difficulty in swallowing was marked, the disease was so advanced as to be incurable. In the earlier and more hopeful stages, the complaint was often one of only slight and transient sticking of food during deglutition. Finally, there were two important and surgically remediable causes of dysphagia in the newborn. The first was congenital atresia of the œsophagus, and the second, a good deal rarer, was vascular compression of the œsophagus in association with anomalies of the great vessels. The latter was the condition sometimes alluded to as "dysphagia lusoria," and the obstruction could be caused either by a reduplicated aortic arch encircling the œsophagus, or by compression of the gullet by a right subclavian artery arising far back on the aortic arch.

The radiological investigation of dysphagia was reviewed by Dr. C. P. Pickard (Dundee). There was seldom any difficulty in recognising gross œsophageal disease, but the detection of slight alterations in motility and in mucosal pattern demanded observation in different positions and postures, especially when some abnormality at the gastro-œsophageal junction was suspected. Barium should not be used in the neonatal atresias, or in the aged, because of its toxic effects on the bronchopulmonary tree. One of the iodised oils was a satisfactory and safer substitute.

Mr. R. R. Woods (Dublin), discussing endoscopy in the diagnosis of dysphagia, thought that direct laryngoscopy would establish the diagnosis in most cases of pain during the act of swallowing, and that œsophagoscopy would do so in most cases of obstruction. He strongly believed that the thoracic surgeon should be his own endoscopist, for in no other way could he obtain sufficiently accurate information about the size, position, and nature of a growth to enable him to determine the best treatment. In the management of inoperable malignant disease of the gullet, Mr. Woods advocated the insertion of a flexible tube of stainless steel wire.

Mr. R. H. Franklin (London) spoke on the diagnosis and treatment of congenital atresia of the œsophagus. A number of varieties had been described, but the commonest (80%) and the most important surgically was the type in which the upper part of the œsophagus ended blindly at the level of the arch of the azygos vein, and the lower part opened into the trachea at or near the bifurcation. This error of development could be expected once in every 2500 births, and the symptoms to which it gave rise were so characteristic that diagnosis should be simple. The infant had recurring attacks of choking and cyanosis when the accumulated œsophageal mucus spilled over into the larynx. This phenomenon became worse when attempts were made to feed the child, and eventually a fatal pulmonary infection developed. The diagnosis could be made by noting the arrest of a well-lubricated rubber catheter at a distance of 10–12 cm. from the alveolar margin. X-ray examination showed the presence of air in the stomach and intestine, indicating the fistulous communication with the trachea, and the introduction of 1–2 ml. of 'Lipiodol' into the upper œsophageal segment demonstrated the block. Mr. Franklin thought that the most rational and successful of several alternative operations was early primary anastomosis after extrapleural exposure of the œsophagus. In the rarer type in which the distal segment did not communicate with the trachea, he had found the area of obliteration so extensive that anastomosis was virtually impossible.

Prof. John Morley (Manchester) dealt with the treatment of pharyngeal pouch. He thought that operation should be avoided until the pouch was large enough to produce such "nuisance" effects as audible gurgling after meals, and attacks of choking caused by overflow when the patient lay down. On the other hand, too great a delay led to serious malnutrition, for the distended pouch and the distortion of the œsophagus made the passage of adequate food impossible. A further danger of delay was the development of squamous epithelioma in the pouch, a complication he had twice encountered. In his view there was no place for such palliative measures as inversion or suspension of the pouch; it should be removed in one stage, and the pharynx repaired. He doubted whether the fashionable two-stage resection had really ever been necessary; it was now certainly outmoded, and the common approach along the anterior border of the sternomastoid was much more unsightly than a transverse collar type of incision. The operation was carried out under a cover of penicillin. If the patient was seriously emaciated, a preliminary gastrostomy two weeks before operation allowed the nutritional state to be corrected. In his series of 33 cases, Professor Morley had had no fatalities, and a transient postoperative fistula on only 2 occasions.

Mr. Geoffrey Wooler (Leeds) gave an account of the management of cardiospasm and the other disturbances at the cardio-œsophageal junction. Cardiospasm could give rise to symptoms at any age, and lead to emaciation as profound as in cancer. The development of the complete radiological picture was preceded by a change in the motility of the lower part of the œsophagus, and this change could sometimes be detected on X-ray examination. In the majority of cases the symptoms of cardiospasm were relieved, and the size and motility of the œsophagus restored, by dilatation of the cardia, under anæsthesia, with Negus's hydrostatic bag. The Heller type of operation should be reserved for patients in whom the gullet was grossly elongated or had prolapsed through the hiatus, or in whom there was an accompanying hiatus hernia. When there was a hernia, this was repaired as well; and occasionally a deliberate repair of the hiatus had to be carried out after dilatation, because of secondary incompetence, with reflux œsophagitis or peptic ulceration. Hiatus hernia as a cause of dysphagia was nearly as common as carcinoma. The type most often requiring surgery was the sliding hernia of the stomach into the thorax; the para-œsophageal type was seldom associated with reflux of gastric juice. Mr. Wooler believed that all fibrous strictures of the lower œsophagus were secondary to peptic ulceration of the gullet; the stenosis could involve a very long segment of the tube, and, particularly in children, could supervene very rapidly. For this reason, early operation was indicated in children with symptoms of reflux œsophagitis. In adults, the necessity for operation was determined by the severity of the symptoms. Repair should be carried out through the chest, and if there was active ulceration at the time of operation, the ulcer should be resected.

Mr. Vernon C. Thompson (London) discussed the treatment of primary carcinoma of the œsophagus. The surgical ideal was resection of the tumour and restoration of the continuity of the alimentary canal, in most cases by gastro-œsophageal anastomosis within the chest after mobilisation of the stomach. Multiple-stage operations and the elaboration of an ante-thoracic œsophagus were outmoded. Resection should be attempted as a palliative measure, even in the presence of obvious glandular enlargement; but if it was quite impossible, a short-circuit should be established. It was most important that the patient should be able to swallow when he regained consciousness. Except for growths actually involving the cardia, he preferred a right-sided thoracotomy, preceded by a mid-line laparotomy through which the stomach was completely mobilised from the œsophagus to the pylorus, the œsophageal hiatus was stretched, and the anterior part of it divided between sutures. The results of resection were depressing. The operative mortality was high, and the recurrence-rate was also high because of the essential malignancy of the lesion and the usual delay in diagnosis.

In the discussion, Mr. Norman Tanner (London) considered that in the repair of a hiatus hernia, an abdominal approach was preferable to a thoracic operation; it was easier and allowed a more adequate exposure of the defective diaphragmatic crus. He reserved the thoracic approach for cases in which there was considerable shortening of the œsophagus.

Mr. Franklin thought that there were still many controversial points about hiatus hernia and œsophageal regurgitation. He pointed out that regurgitation was usual in infants after overfilling of the stomach, but, on the other hand, œsophagitis, ulceration, and stricture were rare. He had also encountered spontaneous recovery in cases of quite extensive œsophageal stricture in children. He too had found a right thoracotomy excellent for the resection of tumours of the middle part of the thoracic œsophagus. He believed that short-circuit operations gave just as good results in the elderly as resection.

Mr. A. M. Abrahams (Liverpool) had noted the persistence of dilatation and flaccidity after Heller's operation for cardiospasm. Mr. Wooler considered that if œsophageal motility was not restored, the failure was due either to incomplete division of the circular muscle fibres of the lower end of the œsophagus or to degeneration of Auerbach's plexus. He believed that the abdominal repair of hiatus hernia was often inadequate and was attended by a considerable recurrence-rate.

SOCIAL MEDICINE AND OCCUPATIONAL HEALTH

President: Dr. Andrew Topping

Necessity for Preventive Approach to Medical Practice

The subject of this discussion might well have been "the need for simplification and coördination," so closely did all the speakers agree on this.

Prof. Leslie Banks (Cambridge) opened with a description of the history of local-authority health services, and asked whether we still believe that the prevention and cure of disease are distinct entities. He suggested that prevention, diagnosis, and treatment and aftercare must now form one continuous process, and that we should revise our undergraduate and postgraduate teaching accordingly. Professor Banks continued:

"To question the need for maternity and child-welfare services and the school medical service in their present form is to invite a storm of protest and the confident assertion that the facts speak for themselves. Indeed they do. An infant-mortality rate of 26 and a maternal-mortality rate of 0·7 show that the years of endeavour have at last borne fruit. They also show that having defeated the enemy the great army of workers could now be demobilised retaining only a highly skilled skeleton staff. These sentiments may be unpopular, but I do suggest quite seriously that the time has come to merge the maternal and infant-welfare services with the hospital obstetric and pædiatric services. A similar case could be made for the aftercare of tuberculous and mental patients to be conducted from the hospital rather than by the local health authority."

The many local administrative bodies might well be replaced by an all-purpose health and medical care authority with executive responsibility for local health services and for hospital and general medical services. The hospital has become the focal point of our medical services and is likely to remain so for a number of years to come. Health centres should be associated with the hospital. He deplored the past neglect of the salaried medical officer in central and local government service by his clinical colleagues, for this has resulted in a dearth of competent medical administrators when they are most needed. The work of the deans of the great medical schools has shown that it is possible for a doctor to be a good administrator, and Professor Banks thought that the medical officer of health could play a similar part in the coördination of local medical services. An effective first step would be to give him an honorary contract on the staff of the local hospital group as home care physician, charged with the coördination of the many agencies responsible for prevention, home care (especially of the chronic sick), and aftercare. Such an appointment would be of great value both to the general practitioner and to the consultant. The cure of disease has now become a major interest of the State. If the practice of medicine is to be kept at an economic level, and incorporate the benefits of progress, the medical profession must pay more than lip service to the adage that prevention is better than cure, for this applies to the health of the medical profession as well as to the health of the nation.

Dr. RICHARD SCHILLING (Manchester) also emphasised that prevention is better and cheaper than cure, and asked for a broader approach to the problem of the burden of sickness. He thought that the general practitioner, in particular, should play a much greater part in the prevention of disease, both in the individual and in the group. The toxicological hazards in industry have been solved by engineering techniques, and the present-day problems are, indeed, more social than medical. We have, perhaps, too many diplomas, and the time has come to consider whether the teaching of public health and industrial medicine should be unified. In factories curative and preventive medicine must be combined, and Dr. Schilling produced evidence of the benefits of immediate treatment by the industrial medical service, and, incidentally, of the value of keeping good records. In the small industry the bulk of the work should be done by the general practitioner, but he must be trained from the day he starts his medical studies.

Dr. JOHN McCANN, in a speech remarkable for its breadth of vision, pointed out that the good doctor has always been concerned with prevention and treatment. The State, he said, exists to serve society, and mere materialism is not a philosophy. Man's human dignity and spiritual nature must be recognised. He thought the time would come when the patient would say "keep me in good health, doctor"; and no government agency could possibly replace the family doctor, with his detailed knowledge and the confidence of the patient. The doctor is not a diagnostic machine, and Dr. McCann hoped that the time would never come when the public regarded health as a commodity to be supplied on demand. He insisted that the general practitioner and the personal health services must be brought together in the future. The general practitioner should be a key worker in the whole scheme of health, and he hoped that modern society has not made that relationship impossible. Although the world has changed and the tempo of life has changed, human nature has not changed.

Dr. J. A. HARBISON (M.O.H. for Dublin) agreed that the general practitioner should play his part in prevention, but he must have the help of the whole team and become part of it. The team also must take an interest in the general practitioner. Dr. Harbison had some pointed comments to make on health education, and said that the risk is that we are now producing a half-educated community. The remedy, full education, requires the help of the general practitioner. He thought that the medical curriculum for the embryo general practitioner might well be changed to include less major surgery and more knowledge of home conditions of the patients.

Dr. BRIAN PRINGLE (Dublin), speaking from the viewpoint of the industrial medical officer, said that the practice of medicine in the factory was a good experiment in social and preventive work. Just as the cardiologist relied on exercise tolerance tests so could society accept work tolerance tests carried out by the industrial medical officer.

The PRESIDENT pointed out the dangers of a wrong orientation of medical education, and called on Miss Ethel Cohen to describe her experience in the United States. Miss COHEN said that at Tufts Medical College, Boston, it was recognised some years ago that there was a need to teach social philosophy, and for the medical student to recognise the personal problems of the patient. This teaching should not be limited only to home visits, because this may lead to a false emphasis on economics and poverty, whereas interpersonal problems may occur at all levels of society.

Dr. JOHN EUSTACE (Dublin) also spoke as an industrial medical officer, and referred to the value of industrial sick absence records, particularly in revealing the causes of psychosomatic disorders, both at home and at work. In his view the contribution of world unrest to the increased incidence of this type of illness could not be ignored by doctors.

PSYCHIATRY

President: Dr. DESMOND CURRAN

Psychiatric Disorders in Later Life

Dr. R. S. ALLISON (Belfast) emphasised the importance of toxic factors and biochemical disturbances in producing acute though reversible states of confusion or delirium. As ætiological agents, anoxæmia and dehydration were apt to be overlooked; yet after long operations they were often responsible for a severe confusional episode. The prompt treatment of postoperative vomiting was important in prophylaxis. Though most cases in this group were potentially reversible, long-continued anoxæmia could result in permanent dementia: thus in one patient repeated hæmatemeses had caused cortical atrophy. In elderly diabetics fre

attacks could lead to symptoms

senile dementia, and in these cases insulin dosage should be adjusted so as to keep the blood-sugar at a relatively high level. Elderly hypochondriacs might become confused after taking too many stomach powders, but they recovered rapidly with treatment. Cerebral tumour presented difficulties in diagnosis because papillœdema and headache were often absent. The grandiose form of general paralysis was uncommon nowadays, and as the blood Wassermann reaction was sometimes negative the cerebrospinal fluid should be investigated in every case of presenile dementia. A history of head injury was rarely obtained in subdural hæmatoma, but the characteristic fluctuations in the clinical picture usually suggested the diagnosis. The separation of cases of presenile dementia with focal signs, such as Pick's and Alzheimer's disease, from the main body of dementias in old age was justified—if only because it drew attention to the group of disorders, resembling the presenile dementias in their focal symptomatology, which could be alleviated by treatment. Yet he was doubtful whether the parieto-occipital syndromes such as disturbances of spatial orientation and of the body image, reported in these conditions as well as other organic psychoses, ever occurred in the absence of clouding of consciousness.

Dr. **Martin Roth** (Chichester) described an investigation of 386 patients over the age of 60. They fell into five groups which were distinct in their natural history: affective psychosis (forming over half the cases), senile psychosis (about a quarter of the cases), and three smaller groups—paraphrenia, arteriosclerotic psychosis, and acute confusion. Within six months of admission to hospital almost 60% of patients with affective disorder were discharged, while about the same proportion of senile psychotics were dead. Most paraphrenics remained as inpatients, while the acute confusional group showed an equal proportion (42%) of dead and discharged. Cases of arteriosclerotic psychosis were mostly dead or inpatients, in approximately equal proportions. These distinctive patterns of outcome in the five groups were sustained in four of the disorders at two years after admission. The discharges had risen slightly among affective illnesses, while deaths in the senile group had risen to 80% of the total admitted. Most paraphrenics remained as inpatients, and there had been a slight rise in the proportion of discharges among patients with confusion. Only cases of arteriosclerotic psychosis revealed a change in pattern; the deaths had risen steeply to 70% to make the two-year outcome only a little better than that of senile psychosis. The figures had been derived from patients consecutively admitted during three separate years, and the trends described had been consistent. Dr. Roth felt that these differences in the natural history of the clinical groups should be taken into consideration in the planning of units designed for cases of mental disorder in old age. The theoretical interest of the findings was that they showed clear differences in the natural history of the functional group (affective and paraphrenic psychoses) on the one hand, and the organic group (senile and arteriosclerotic psychoses) on the other. These differences in outcome were shown to be independent to a large extent of age differences between the groups, and psychological tests had also been shown to differentiate sharply between them. The combination of functional symptoms such as depression and mania with dementia certainly occurs, but in the case-material studied, the proportion was small enough to make it probable that in such patients there is a coexistence of two relatively distinct disease processes. Much evidence had recently accumulated to support this interpretation.

Prof. **J. Dunne** (Dublin) supported Dr. Allison's plea that more attention be paid to the acute recoverable conditions in old age produced by toxic factors. He had recently studied a patient who had become acutely disturbed after taking excessive doses of ephedrine to cope with his asthma.

Dr. **K. C. Bailey** (Taunton) believed that myxœdema was often a cause of apparently irreversible dementia in late middle and old age.

Dr. **E. A. Bennet** (London) had often met in this age-group patients with psychoneurosis who had made good adjustment to life after neurotic breakdown in adolescence. The recurrence of neurosis in old age often responded to psychotherapy.

Dr. **R. H. Moore** (London) wondered whether the high mortality in cases of senile psychosis could be due to the use of heavy sedation in such cases. Dr. **Allison** in reply agreed that heavy sedation was fraught with risk in old patients.

OTORHINOLARYNGOLOGY

President: Mr. T. O. **Graham**

Antibiotics

Mr. **R. B. Lumsden** (Edinburgh) said that in all infections of the ear, nose, and throat, penicillin was the antibiotic of choice, despite the disadvantage of parenteral administration. Maximum dosage should be used from the start because the formation of resistant organisms was thereby discouraged. Staphylococci, normally the most sensitive organisms, can become the most highly resistant to penicillin. Penicillin could often be usefully combined with sulphonamides especially in meningeal infections. Toxic reactions to penicillin were uncommon, but local lesions may develop in the mouth after the use of penicillin lozenges, which should not be given for longer than 48 hours. The newer antibiotics more commonly produced these oral lesions by inducing a fungus overgrowth. Antibiotics also had their place in prophylaxis—e.g., in operations on patients with rheumatic carditis or nephritis—and he had found that they gave useful cover to a fenestration operation. Though these drugs were a great help in acute otitis media, fundamental surgical principles still applied, and operation had its place. The day-to-day appearance of the drumhead and the evaluation of hearing were important guides; myringotomy should not be delayed when indicated. Whenever possible the infecting organism should be identified, otherwise treatment was empirical. If there was no improvement after 48 hours, treatment should be changed. Acute mastoiditis has become much less common and complications were rare. Chronic suppurative otitis media was little improved by the antibiotics, but active treatment of the acute infection should reduce the number of chronic cases in time.

Mr. **T. G. Wilson** (Dublin) thought that the great improvement which coincided with the introduction of antibiotics might be due, in part at least, to a decline in virulence of the causal organisms. Virus diseases continued to increase however, and acute laryngotracheobronchitis had replaced diphtheria as a dread disease of children. Penicillin, the first antibiotic, was still the best and the least likely to promote drug resistance. The incidence of laryngeal complications in pulmonary tuberculosis had been spectacularly reduced, partly by streptomycin, but he did not think streptomycin should be used in very early tuberculous laryngitis until rest and calciferol had been tried. Streptomycin should be combined with *p*-aminosalicylic acid; each blocked a different metabolic pathway, and resistant strains were less likely to develop. The recommended dosage of streptomycin was 1 g. daily for 3 months. Vestibular responses should be tested at least once monthly during treatment. Dihydrostreptomycin often caused cochlear degeneration, and Mr. Wilson thought its use was unjustified.

Discussing the topical use of antibiotics, Mr. M. A. O'BRIEN (Cork) said that 10% chloramphenicol in propylene glycol was very effective in *otitis externa* and meatal furunculosis. Local treatment might helpfully be supplemented by parenteral penicillin for 72 hours. Local chloramphenicol may be useful in chronic suppurative otitis media without cholesteatoma formation. Terramycin was rather unstable for topical application. 5% aureomycin in lactose was valuable for ridding mastoid and fenestration cavities of secondary infection. Local treatment of the nasal cavity was seldom successful in the early stages of an acute infection, but when localisation had taken place autodisplacement with solutions of penicillin or aureomycin could be used. Chronic sinus infections, especially of the maxillary antrum, responded well to weekly lavage and instillation of 10% sulphathiazole and 20% sulphanilamide in a suitable base. He had found this a useful method in children. The results of local application in infections of the mouth and pharynx were disappointing, presumably because the antibiotic was only in contact with the lesion for a short time.

In the discussion Mr. W. H. B. MAGAURAN (London) said that radical surgery was seldom necessary nowadays. He described a treatment of sinus infection which he had found successful: a small opening was made in the floor of the sinus, the infective exudate was aspirated and replaced by the appropriate antibiotic as determined by bacteriological examination. This simple manœuvre was generally effective, and if reinfection occurred, irrigation and instillation of antibiotics could be performed through the scar.

Mr. R. R. WOODS (Dublin) said that though penicillin was invaluable in acute otitis media, it must be given early and before pus was present. When pus had formed, drainage was necessary to avoid the danger of an adhesive type of infection and deterioration of hearing.

Ménière's Syndrome and Simulating Conditions

Mr. C. S. HALLPIKE (London) said that for information upon the symptomatology and natural history of Ménière's disease it was seldom necessary to go beyond Ménière's original papers. Since Ménière's time, however, we had acquired additional knowledge about the histopathology of the disease and its physical signs. It was now well established that the essential lesion consisted of a distension of the endolymphatic sac without evidence of infection or trauma. In a number of cases in which the difficulties of histological examination had not been too great, it had been possible to show changes in the hair cells of Corti's organ which seem to explain the deafness and characteristic distortion of hearing. In addition we now had at our disposal a number of valuable new tests of vestibular and cochlear function; particularly useful were the caloric tests, carried out according to a technique described by Fitzgerald and Hallpike in 1942, and the loudness-recruitment test. This latter test always gave positive results in Ménière's disease and was, therefore, considered to be pathognomonic of a lesion of the end-organ of hearing. Histological examination of the temporal bones in cases of Ménière's disease had not always been successful in demonstrating a lesion of the hair cells owing to the presence of post-mortem histological artefacts. Recent technical improvement, however, had reduced these artefacts, and Mr. Hallpike showed slides illustrating early pathological changes in the hair cells in a case of Ménière's disease. Although the clinical and pathological identity of Ménière's disease had now been clearly established, it was still the practice to include under the undiscriminating title of Ménière's syndrome various other types of organic vertigo which conformed only vaguely to its established symptomatology and pathology. It was hoped that further knowledge would enable these types of vertigo to be separated from Ménière's disease. Mr. Hallpike referred to a recent investigation by Dr. M. R. Dix and himself into the clinical features and morbid anatomy of a particular form of positional nystagmus originally described by Bárány. They had been able to show, on clinical evidence alone, that the disorder was caused by a lesion of the otolith apparatus within the labyrinth. The condition was typically unassociated with deafness or vestibular dysfunction, objective or subjective, apart from a particular type of paroxysmal nystagmus occurring in certain critical positions of the head. Other evidence of neurological disease was invariably absent, and the disorder nearly always ran a benign course. The lesion therefore, was thought to be a self-limiting one confined to the otolith apparatus; its possible causes were chronic infection, trauma, or vascular changes. The paroxysmal character of the nystagmus and the benign course of the disease suggested that this condition should be known as the benign paroxysmal type of positional nystagmus. Mr. Hallpike's slides of histological preparations of the labyrinth from a typical case showed chronic tissue changes in the maculæ of the saccule and utricle, thus confirming the clinical evidence and the view of Bárány.

Mr. E. R. GARNETT PASSE (London) discussed the syndrome from the point of view of the vascular system and its nerve-supply. The increased labyrinthine tension in Ménière's syndrome was difficult to explain because there was no secreting layer, but it may be due to an increase in permeability of the labyrinthine blood-vessels which are under the control of the sympathetic-parasympathetic balance. He had performed 200 sympathectomies, the results of which seemed to support this view. Further work was being done to see if sympathetic stimulation did increase the production of endolymph. The sympathetic supply to the internal auditory artery came from the second thoracic segment, and the parasympathetic supply from the geniculate ganglion.

Mr. F. A. MCLAUGHLIN (Belfast) mentioned some of the conditions which could cause confusion in diagnosis. Trauma may produce symptoms like those of Ménière's syndrome: syringing of the ear, fractures of the base of the skull, and blast injuries were the commonest types. Acoustic neuroma and other tumours in the cerebellopontine angle may also cause difficulty. Vestibular nystagmus could often be differentiated by the history and the absence of signs of aural disease. There was no doubt that strong emotional upset could produce prostration and vertigo, and the mechanism here was probably vasomotor. Certain toxic substances—e.g., quinine—could produce a similar picture, but here the change was peripheral, and perceptive deafness developed in time. Streptomycin was a well recognised cause of vertigo and deafness. Doses of over 2 g. a day seemed likely to produce damage, but if the drug was stopped at the first signs, recovery could be complete in many cases. Mr. McLaughlin suggested a dose of 10 mg. per lb. body-weight per day. He thought the use of dihydrostreptomycin was quite unjustified. Treatment in Ménière's syndrome should start with sedatives, rest, and belladonna. Any focus of sepsis in the ear, nose, throat, or elsewhere should be dealt with. The anti-histamine drugs could help some patients. Finally, surgery had to be considered if conservative measures failed. Sympathectomy, as suggested by Mr. Garnett Passe, might prove to be the best surgical treatment.

INTERNATIONAL CONGRESS OF PHYSICAL MEDICINE

THIS was the first congress to be held under the uspices of the International Federation which had onferred the honour of arranging it on the British ssociation of Physical Medicine. Its organisation was n the hands of a British board of management, with he Duke of Gloucester as patron, Lord Horder as resident, Dr. Philippe Bauwens as chairman, and Dr. A. C. Boyle as honorary secretary of the executive ommittee. National representatives were nominated y 14 countries, and some 20 countries were represented.

The congress was officially opened at King's College, ondon, on July 14 by Marshal of the Royal Air Force ord TEDDER. He said that life was not merely to be live, but to be well and to live in harmony with one's urroundings. He thought that the quickest road back o health lay through physical medicine. He had seen ehabilitation at work in the Armed Forces, and he elieved that its success lay in self-help and in the fact hat the layman had been made a partner rather than a atient. He then lit the ceremonial lamp presented y Lord Horder. Mr. IAIN MACLEOD, Minister of Health, welcomed the delegates. He had been particularly mpressed by the way in which physical medicine prevented chronic suffering and ill health among the aged, and enabled them to remain within their own family circle. Prof. FRANK KRUSEN (United States) spoke for the International Federation, and paid tribute to Lord Horder, Mr. Bernard Baruch, and the late Dr. Richard Kovacs for their part in stimulating interest in physical medicine. He then invested Lord Horder with the presidential badge presented by Mr. Bernard Baruch.

Lord HORDER reminded his audience that young men see visions, old men dream dreams. For physical medicine "the sky's the limit," but only if its practitioners realise that physical medicine is an integral part of medicine and must remain so. He then used the gavel presented by Mrs. Kovacs in memory of her husband. Dr. S. CLEMMESEN (Denmark) and Prof. K. M. WALTHARD (Switzerland) expressed the thanks of the foreign delegates for their welcome.

Scientific Discussions

PHYSICAL MEDICINE IN THE PAST DECADE

Professor KRUSEN, speaking of the amazing advances in the last ten years, said that the practice of physical medicine was no longer founded on an empirical basis. The new specialty of physical medicine and rehabilitation has been integrated. The wisdom, foresight, and generosity of Mr. Bernard Baruch had been a major force in bringing into being the new specialty, in which his father, Dr. Simon Baruch, had been a pioneer. Advances had been made in dosiometry, the techniques of thermotherapy and electrotherapy, the use of microwaves, ultrasonic energy, and electromyography, of progressive-resistance exercises, occupational therapy in rehabilitation, and the teaching and training of young men in the specialty and in research work.

Dr. CLEMMESEN, reviewing progress in Denmark, emphasised the need for thorough diagnosis and proper prescription for treatment. Rheumatology and physical medicine could not, he thought, be separated.

Dr. V. E. KLARE (Vienna) mentioned research work done in his country on low- and high-frequency therapy and on ultrasonics. The work of rehabilitation and resettlement had been stimulated by the visit of Dr. Howard Rusk.

Dr. F. D. HOWITT (London) described the rôle that physical medicine played during the late war in the fighting services and the Emergency Medical Service. He showed how it had helped to make use of every available man and woman by upgrading the substandard youth to fighting capacity, by the creation of physical-development centres, by advising on the medical aspects of physical training and of purposeful training for the specific requirements of different arms, and by restoring to maximum capacity in the minimum of time the military and civilian casualties. In the modern hospital service the physical-medicine specialist takes full clinical control of such conditions as chronic rheumatism and other medical disorders of the locomotor system, and also advises his hospital colleagues on the value and application of physical treatment.

A profitable liaison had been established with the medical and social services of industry. Physical medicine had been translated from a therapeutic to a clinical specialty, and was established as an integral part of general medicine.

REHABILITATION AND RESETTLEMENT

Certain aspects of this concept were discussed by Dr. F. S. COOKSEY (London), who spoke on vocational settlement in Great Britain. He stressed the need for greater interest on the part of medical practitioners; they must initiate appropriate measures for rehabilitation and resettlement at the onset of the illness, and give guidance until the process is complete. He pointed out the need for closer integration between the hospital and the industrial health services, and for treatment facilities outside working hours to avoid unnecessary loss of wages and production. The resettlement of the disabled housewife and the chronic sick in their homes makes them independent of the help of others and frees workers for industry.

Dr. A. J. MARTIN (London) described the resettlement conferences conducted by the physician in charge of rehabilitation at the Royal Free Hospital. It was important to establish a close and personal relationship between the patient, the medical officer, the medico-social services, and the district resettlement officer of the appropriate labour exchange.

Squadron-Leader C. B. WYNN-PARRY described the duties of medical officers in charge of medical units in the R.A.F. both in obtaining the greatest functional recovery, and in guiding the patient in the selection of suitable civilian employment. He discussed the method employed, and he too emphasised the need for close personal contact between the doctor, the district resettlement officer, and the patient. The function of resettlement and rehabilitation is to guide the patient in the making of his own decisions.

Dr. G. GINGRAS (Montreal) described the working of a rehabilitation centre operating under the auspices of the Rehabilitation Society for Cripples.

Mr. LIONEL COSIN (Oxford) described the rôle of physiotherapy in the treatment of the aged. He pointed out that only by the repeated assessment of the pathological, psychological, and sociological factors and their inter-relationship can an accurate estimate be made of the physical factor in the disability of old people. On this basis an accurate economic and therapeutically sound programme of rehabilitation can be drawn up, and individual contentment, independence with social integration, and often some degree of economic freedom can be obtained.

The same problem was dealt with by Dr. V. A. PORSMAN (Copenhagen) who discussed the causes of invalidism among old people, and gave examples of successful rehabilitation. He also pointed out the need for close coöperation between physiotherapists, nurses, occupational therapists, and specialists in physical medicine.

THE RHEUMATIC DISORDERS

Dr. F. Dudley Hart (London) gave a balanced review of the place of endocrine preparations in chronic rheumatic disorders. He showed that, in general, the evidence is against a primary endocrine dysfunction in the rheumatic diseases. Dr. Francis Bach (London) discussed the use of cortisone as an aid to physical treatment in the rheumatic disorders. He pointed out its value in gout, rheumatoid arthritis, and the stiff and painful shoulder and polyarthritis of the elderly. But there are dangers associated with it, and though it is a valuable aid, it is rarely a substitute for physical treatment or for surgical intervention.

Dr. E. W. Lowman (New York) gave a preliminary report on the feasibility of rehabilitating "the chronic rheumatoid derelict" by the use of cortisone and physical medicine. The maintenance dose of cortisone should be kept below 75 mg. per day. The drug should not be expected to control joint symptoms caused by the secondary mechanical hypertrophic changes. The real objective in rehabilitation was to give functional training towards proficiency in those activities necessary to self-sufficient living. He spoke of the wheel-chairs, crutches, braces, and other devices which must be made to suit the needs of individual patients.

Prof. J. Michez (Brussels) gave a clear and orthodox review of physical treatment in rheumatoid arthritis.

Dr. W. A. Fell (Cambridge) described a study of the regions to which pain is referred from the hip joint; these corresponded with the anatomical pattern of innervation, and Dr. Fell discussed the effect of infiltrating the appropriate area of the capsule with procaine, followed by a minor manipulation to increase range of joint movement. Dr. Hugh Burt (London) presented the results of a careful and detailed investigation undertaken to determine whether physical measures have a place in the treatment of the painful shoulder. He concluded that there are indications for physiotherapy. The most important object of treatment is relief of pain; mobilisation is less urgent, for spontaneous increase of movement usually occurs when pain disappears.

Dr. J. M. Poal (Barcelona) showed a new device for the localised treatment of the cervical spine. By using traction alone, or in conjunction with other therapeutic measures, he claimed excellent clinical results. His apparatus consisted of a U-shaped tube resting on the patient's shoulders. This applied traction by means of two gears, with a lever to each, joined to two slings, adapted to the occipent and the inferior part of the maxilla—an ingenious invention of modern Spain.

The many papers devoted to new clinical concepts and research included one by Prof. L. J. Michotte (Brussels) on low back pain, of which he listed 47 causes. He asked the question: "Is herniation of the nucleus pulposus the cause of low backache and sciatica?" He answered it by saying that low backache is caused by tearing of the annular ligament, and sciatica by the expansion of the nucleus out of its cavity and by compression of the nerve-root. The sensory innervation of the annular ligament of the disc between L4 and 5 is derived from the spinal ganglion L2, and that of L5–S1 from the ganglion L3. A lesion of the annular ligament at the level L4–5 or L5–S1 may therefore irritate the sensory termination of the recurrent spinal nerve arising from the level of L2–3, and thus provoke pain in the lower back.

Studies on the permeability of the synovial membrane were described by Dr. W. D. Paul and Dr. J. R. Routh (Iowa City).

ELECTRODIAGNOSTIC METHODS

An electromyographic investigation on muscular fatigue in man was presented by Dr. Arne Lundervold (Oslo). The muscles in the upper extremities were examined electrographically in 37 healthy persons performing tapping movements. The duration and force of contraction in separate muscles, as well as the number of muscles taking part in the movement, were dependent on the rate of tapping. The more rapid the tapping the greater the number of muscles brought into play, and the more forceable the contraction of each muscle. If the subject became tired and the rapidity of movement decreased, there was an increase both in the number of muscles and in the force of contraction of each individual muscle engaged in the operation. Muscle fatigue was assumed to occur when the restitution phase in the muscle cells became too long in proportion to the time available, so that the contractability for that reason was reduced.

Dr. J. Lefebvre (Paris) read a valuable paper on chronaxie in electrodiagnosis, and Dr. E. Kugelberg (Stockholm) discussed electromyography in the differential diagnosis of neuromuscular disorders. Dr. Bauwens described some technical advances in electrodiagnosis.

PHYSICAL MEASURES IN DIAGNOSIS AND TREATMENT

Dr. Howard Rusk (New York) read a paper on Physical Medicine and Rehabilitation: A Service to Medicine and the Community. He stressed the responsibility of the medical profession to the community. Mr. Bernard Baruch had said that the increase in a man's life span during the past 50 years had had more profound medical, economic, and social implications than such things as atomic energy, air transport, and modern communications. Medical science has added years to life, and now we must add life to those years, said Dr. Rusk. We must help the people whose years we have lengthened to lead useful and dignified lives. He described the rôle of the general practitioner, the diagnostic clinic, and the hospital. One in five of our hospital beds can profitably be used for rehabilitation and convalescence. The hospital should be the centre of the rehabilitation services, and with these services should be linked others providing for or leading to full or selective employment, sheltered workshops, home care, housekeeping services, industrial homework, and colonies for the disabled. The needs of the ageing patient can add to the nation's productivity if he is placed in a job within his capacity. Keeping the elderly population as an active part of our economy will be one of the concerns of preventive medicine of the future. He quoted a hospital administrator as saying that 30% of the jobs in his hospital could be done by disabled people. He believed that these people should be in hospital as workers leading happy and contented lives, not as patients.

Dr. Harold Balme (London) spoke about rehabilitation and its international relations.

Other Activities

Delegates paid a visit to Aldershot where they saw a demonstration of physical education by boys and girls from London County Council schools. Lieut.-Col. J. B. M. Milne described the Pulheems method of physical assessment, and a demonstration of battle physical training was given.

An historic and scientific exhibition had been planned by Dr. C. Shields. The Wellcome Medical Museum showed a fascinating exhibit illustrating the developments of hydrotherapy, massage, and remedial exercises, and the therapeutic use of electricity and radiant energy. Among the other exhibits were electronic equipment developed at St. Thomas's Hospital, shown by Dr. Bauwens, and self-help devices and mechanical aids for the disabled from Dr. Rusk's centre in New York. Mrs. Guthrie Smith showed a bed-chair made of light tubular steel, and consisting of a back and two long arms designed to support the patient in comfort and security and yet afford enough mobility to allow change of posture and increased range of knee and leg movement—an ingenious apparatus which can also be used for rehabilitation and transport. A kitchen unit developed at King's College Hospital for the assessment and training of the disabled housewife aroused much interest.

A series of very interesting films was shown; to name only one, Dr. G. D. Kersley showed a film on hydrology which had been made in the Bath area group of hospitals. After a general summary of rehabilitation methods, the film showed how hydrology could be used to supplement these methods.

The Congress in Retrospect

The congress demonstrated that physical medicine has been accepted as a specialty within general medicine. It does not detract from orthopædics, neurology, or psychiatry, but gives something new to medicine. The speeches of Sir Cecil Wakeley, F.R.C.S., and Sir James Paterson Ross at the dinner given to the national representatives by the council of the Royal College of Surgeons, and those of Sir Lionel Whitby and Sir Russell Brain, F.R.C.P., at the congress banquet, showed that physical medicine was welcomed by the leaders of medical thought and action as a young and dynamic partner. Physical medicine, it was said, is a discipline which aims above all to help human beings to achieve harmony with their surroundings. Rehabilitation, as a part of physical medicine, was defined as the preparation of the patient, mentally, socially, and vocationally, for the fullest possible life compatible with his abilities and disabilities. Rehabilitation is only as sound as the basic medical services of which it is part. The diagnosis and prognosis must be accurate for it is upon them that the feasibility of retraining is determined.

The physical medicine specialist needs to be a "good doctor" as well as a trained clinician. He is looking at humanity, and particularly at his patient, from what may appear to many of his colleagues to be a new angle. At this meeting there were physicians whose chief interest lay in electrodiagnosis, others whose lives were spent in the day-to-day work of a hospital physical-medicine department, others mainly interested in what used to be termed rheumatology, others who studied the problems of the aged, and others engrossed in administration; but all of them were specialists in physical medicine. There were also a number of young men, already good doctors, who were eager to play their part in the medicine of the future, and there were physiotherapists, occupational therapists, and almoners—all essential members of the team on which successful rehabilitation depends.

The personalities of Lord Horder, Dr. Frank Krusen, and Dr. Howard Rusk will remain vividly in the minds of everyone who attended this congress. This is the medicine of the future, but its disciples must remember and live the warning of their president: *Le malade, toujours le malade.*

F. J. B.

CONGRESS OF OBSTETRICIANS AND GYNÆCOLOGISTS

The 13th Congress of Obstetricians and Gynæcologists was held in Leeds on July 8–11, under the presidency of Prof. A. M. Claye.

In a guest paper on Cancer of the Body of the Uterus Prof. M. A. van Bouwdijk Bastiaanse (Holland) discussed the advantages of operation by the vaginal route. He had an operability-rate of 96·2% and an absolute ten-year cure-rate of 65·1%.

The two whole days and two half-days of the meeting were each devoted to discussion of a single subject, with the aim of enabling a large number of members to speak.

Abnormal Uterine Action during Labour

Prof. G. H. Bell (Dundee) as a physiologist reviewed the means for recording uterine action, and found no method satisfactory for deciding whether the lower uterine segment or cervix behaved passively or actively during labour. He thought it unlikely that progesterone caused the uterus of any species to become quiescent. He accepted the evidence that the pregnant and non-pregnant human uterus reacted differently to the posterior-lobe hormones, but remarked that the cause of the difference required investigation. In animals at parturition both the cervix and body responded to pitocin; but the cervix reacted for only a short time while the body continued to respond, thus suggesting a normal action by the cervix to prevent precipitate delivery. If this applied in man it suggested that exaggeration of this effect would lead to cervical dystocia.

There was no objective evidence that in labour pethidine exerted an antispasmodic effect on the cervix. Any benefit from pethidine might be due to augmentation of activity in the uterine body. Among drugs investigated for antispasmodic activity on the rabbit cervix, isoprenaline and dihydroergotamine were effective, the latter however being inconstant in action. The antispasmodic action of isoprenaline was consistently more distinct on the cervix than on the corpus: but this drug would not be suitable for clinical trial until it had been modified to avert its dangerous vasodepressant effect.

Prof. W. C. W. Nixon (London) showed the histology of the pregnant cervix to demonstrate that about half the tissue was muscular and therefore capable of pharmacological response. He thought it possible that incoordination of uterine action was related to abnormal muscle-collagen distribution. The constant feature in incoördination was prolonged labour; and his standard was labour lasting more than thirty-six hours. Comparison of the incidence of prolonged labour in London with seven different racial groups in other parts of the world showed the influence of age and parity. In all centres there was a higher incidence of prolonged labour in primigravidæ; in London a relatively small proportion had their first pregnancy before the age of 22 years.

In a series of primigravid women judged to be at term the position, length, dilatation, and consistence of the cervix was noted at the time of artificial rupture of the membranes. Where the cervical tissues were softened and the canal short and open, the subsequent induction-delivery interval appeared to be generally short. When, however, the cervix was directed towards the sacrum—the "sacral os"—a prolonged labour always ensued. Whenever labour had lasted longer than twenty-four hours a careful review should be made. For cervical dystocia a drip infusion containing pitocin or glucose or 'D.H.E. 45' had not given constant results. During recent years he had found an increase in the incidence of cæsarean section for labours lasting over forty-eight hours; he now felt that unfavourable cases should be detected earlier, thus shortening the interval before section.

Mr. E. A. Williams (Oxford) described a method of recording intra-uterine pressure changes by 'Polythene' tubing introduced into the amniotic cavity past the presenting part through a Drew-Smythe catheter. An ample portion of tubing lay within the uterus; and the portion outside might be strapped to the thigh, thus allowing complete freedom of movement to the patient in the intervals between pressure recordings. The base-for close coöperation between physiotherapists, nurses, occupational therapists, and specialists in physical medicine.

THE RHEUMATIC DISORDERS

Dr. F. DUDLEY HART (London) gave a balanced review of the place of endocrine preparations in chronic rheumatic disorders. He showed that, in general, the evidence is against a primary endocrine dysfunction in the rheumatic diseases. Dr. FRANCIS BACH (London) discussed the use of cortisone as an aid to physical treatment in the rheumatic disorders. He pointed out its value in gout, rheumatoid arthritis, and the stiff and painful shoulder and polyarthritis of the elderly. But there are dangers associated with it, and though it is a valuable aid, it is rarely a substitute for physical treatment or for surgical intervention.

Dr. E. W. LOWMAN (New York) gave a preliminary report on the feasibility of rehabilitating "the chronic rheumatoid derelict" by the use of cortisone and physical medicine. The maintenance dose of cortisone should be kept below 75 mg. per day. The drug should not be expected to control joint symptoms caused by the secondary mechanical hypertrophic changes. The real objective in rehabilitation was to give functional training towards proficiency in those activities necessary to self-sufficient living. He spoke of the wheel-chairs, crutches, braces, and other devices which must be made to suit the needs of individual patients.

Prof. J. MICHEZ (Brussels) gave a clear and orthodox review of physical treatment in rheumatoid arthritis.

Dr. W. A. FELL (Cambridge) described a study of the regions to which pain is referred from the hip joint; these corresponded with the anatomical pattern of innervation, and Dr. Fell discussed the effect of infiltrating the appropriate area of the capsule with procaine, followed by a minor manipulation to increase range of joint movement. Dr. HUGH BURT (London) presented the results of a careful and detailed investigation undertaken to determine whether physical measures have a place in the treatment of the painful shoulder. He concluded that there are indications for physiotherapy. The most important object of treatment is relief of pain; mobilisation is less urgent, for spontaneous increase of movement usually occurs when pain disappears.

Dr. J. M. POAL (Barcelona) showed a new device for the localised treatment of the cervical spine. By using traction alone, or in conjunction with other therapeutic measures, he claimed excellent clinical results. His apparatus consisted of a U-shaped tube resting on the patient's shoulders. This applied traction by means of two gears, with a lever to each, joined to two slings, adapted to the occiput and the inferior part of the maxilla—an ingenious invention of modern Spain.

The many papers devoted to new clinical concepts and research included one by Prof. L. J. MICHOTTE (Brussels) on low back pain, of which he listed 47 causes. He asked the question: "Is herniation of the nucleus pulposus the cause of low backache and sciatica?" He answered it by saying that low backache is caused by tearing of the annular ligament, and sciatica by the expansion of the nucleus out of its cavity and by compression of the nerve-root. The sensory innervation of the annular ligament of the disc between L4 and 5 is derived from the spinal ganglion L2, and that of L5–S1 from the ganglion L3. A lesion of the annular ligament at the level L4–5 or L5–S1 may therefore irritate the sensory termination of the recurrent spinal nerve arising from the level of L2–3, and thus provoke pain in the lower back.

Studies on the permeability of the synovial membrane were described by Dr. W. D. PAUL and Dr. J. R. ROUTH (Iowa City).

ELECTRODIAGNOSTIC METHODS

An electromyographic investigation on muscular fatigue in man was presented by Dr. ARNE LUNDERVOLD (Oslo). The muscles in the upper extremities were examined electrographically in 37 healthy persons performing tapping movements. The duration and force of contraction in separate muscles, as well as the number of muscles taking part in the movement, were dependent on the rate of tapping. The more rapid the tapping the greater the number of muscles brought into play, and the more forceable the contraction of each muscle. If the subject became tired and the rapidity of movement decreased, there was an increase both in the number of muscles and in the force of contraction of each individual muscle engaged in the operation. Muscle fatigue was assumed to occur when the restitution phase in the muscle cells became too long in proportion to the time available, so that the contractability for that reason was reduced.

Dr. J. LEFEBVRE (Paris) read a valuable paper on chronaxie in electrodiagnosis, and Dr. E. KUGELBERG (Stockholm) discussed electromyography in the differential diagnosis of neuromuscular disorders. Dr. BAUWENS described some technical advances in electrodiagnosis.

PHYSICAL MEASURES IN DIAGNOSIS AND TREATMENT

Dr. HOWARD RUSK (New York) read a paper on Physical Medicine and Rehabilitation: A Service to Medicine and the Community. He stressed the responsibility of the medical profession to the community. Mr. Bernard Baruch had said that the increase in a man's life span during the past 50 years had had more profound medical, economic, and social implications than such things as atomic energy, air transport, and modern communications. Medical science has added years to life, and now we must add life to those years, said Dr. Rusk. We must help the people whose years we have lengthened to lead useful and dignified lives. He described the rôle of the general practitioner, the diagnostic clinic, and the hospital. One in five of our hospital beds can profitably be used for rehabilitation and convalescence. The hospital should be the centre of the rehabilitation services, and with these services should be linked others providing for or leading to full or selective employment, sheltered workshops, home care, housekeeping services, industrial homework, and colonies for the disabled. The needs of the ageing patient can add to the nation's productivity if he is placed in a job within his capacity. Keeping the elderly population as an active part of our economy will be one of the concerns of preventive medicine of the future. He quoted a hospital administrator as saying that 30% of the jobs in his hospital could be done by disabled people. He believed that these people should be in hospital as workers leading happy and contented lives, not as patients.

Dr. HAROLD BALME (London) spoke about rehabilitation and its international relations.

Other Activities

Delegates paid a visit to Aldershot where they saw a demonstration of physical education by boys and girls from London County Council schools. Lieut.-Col. J. B. M. Milne described the PULHEEMS method of physical assessment, and a demonstration of battle physical training was given.

An historic and scientific exhibition had been planned by Dr. C. SHIELDS. The Wellcome Medical Museum showed a fascinating exhibit illustrating the developments of hydrotherapy, massage, and remedial exercises, and the therapeutic use of electricity and radiant energy. Among the other exhibits were electronic equipment developed at St. Thomas's Hospital, shown by Dr. BAUWENS, and self-help devices and mechanical aids for the disabled from Dr. Rusk's centre in New York. Mrs. GUTHRIE SMITH showed a bed-chair made of light tubular steel, and consisting of a back and two long

line for fluid-pressure readings was taken from the level of the symphysis pubis with the patient recumbent. Tracings showed the commencement of labour with normal rhythm; the interference caused by bladder distension; the impetus to uterine action of an enema; and the effect of posture on labour, where the optimum effect was observed with the patient sitting. Failure of relaxation between contractions was observed in association with fœtal distress. It was noteworthy that no instance of hypertonic uterine action had been observed.

Dr. C. N. SMYTH (London) proposed the formation of a committee, national or international, to standardise the meaning of terms employed in obstetric records and to design a labour-record chart suitable for mechanical sorting which could have a world distribution and form the basis of a central file of information. He emphasised the vagueness of words such as "labour." By way of illustrating the value of collected information he showed a graph of the expected duration of labour for patients who had already been in labour for various lengths of time. Dr. Smyth also referred to the controlled "pitocin labour" and emphasised the need for tocographic control of the drip-rate. He pointed out the effect of pressure on the cervix, either manual or from the presenting part, in stimulating uterine contractility.

Prof. R. CALDEYRO-BARCIA (Montevideo) described the experimental methods which he uses with his colleague Prof. H. ALVAREZ to record uterine tension simultaneously in both cornual areas and in the lower body and cervix. The pressure inside the bladder with less than 35 ml. of fluid was recorded to assess the influence of intra-abdominal pressure on the total intra-amniotic pressure. Thus the intra-uterine tension could be estimated. When uterine contractions on both sides were simultaneous and equivalent in force, labour proceeded satisfactorily. With asynchronous activity the contractions were ineffective and labour was slow. The effect of 'Nupercaine' spinal anæsthesia in relieving asynchronous activity, and of adrenaline in increasing irregular activity, was shown. This method was the most satisfactory yet developed for the study of uterine action and for testing new drugs, such as dihydroergotamine.

Miss JEAN HALLUM (Birmingham) reported satisfactory results from dihydroergotamine 0·25 mg. intramuscularly in 40 cases.

Mr. K. S. RICHARDSON (Sydney) reported that dihydroergotamine was suitable, not for the lazy uterus, but for the uncommon incoördinate type, and that dosage should be cautious. Prof. T. N. A. JEFFCOATE (Liverpool) agreed with this distinction. Like Prof. J. CHASSAR MOIR (Oxford) he held that all oxytocics were potentially dangerous. Probably administration in high dilution by a closely supervised drip was the least dangerous method of determining individual dosage.

Pædiatrician's Place in a Maternity Unit

Prof. W. F. GAISFORD (Manchester) as a pædiatrician welcomed the obstetric skill which caused a decline in the number of infants born with intracranial damage liable to produce backwardness. He remarked that the contribution of the pædiatrician to this improvement had been the diminution of pelvic rickets. It was necessary for the pædiatrician to undertake the resuscitation, care, and investigation of the normal newborn infant, in order to acquire skill and knowledge in detecting the earliest signs of disorder and in preventing disease.

His investigations had shown that a binder could contribute to atelectasis; that faulty cord dressings could spread infection; that vernix caseosa should not be washed off; that the routine use of vitamin K reduced the risk of hypoprothrombinæmia; and that early immunisation against tuberculosis and whooping-cough could save lives. He desired control of breast-feeding and believed that preparation should begin early in pregnancy. To this end he advised that a pædiatric sister should attend the antenatal clinic to instruct mothers in preparation for breast-feeding. In the antenatal period the pædiatrician should be consulted in the management of such problems as prematurity, fœtal malformations, hæmorrhagic diseases of the newborn, and toxæmia. Antenatal pædiatrics was an aspect of child health which offered more promise of future development than any other branch.

Mr. F. E. STABLER (Newcastle upon Tyne) said that without definition of status he had for many years found complete harmony in working with pædiatricians. He welcomed the pædiatrician's aid from the earliest stage of pregnancy—indeed on occasion before conception—and his advice on the structure and management of the hospital. In his hospital, at least once a week obstetricians and pædiatricians together went round their departments in consultation. At monthly staff meetings they were joined by the general physician, anæsthetist, surgeon, and pathologist for joint discussion. Mr. Stabler defined the ideal pædiatrician colleague as a good doctor fully acquainted with the physiology and pathology of pregnancy and labour. He must be an obstetrician lacking only manipulative skill in delivery.

Dr. BERYL CORNER (Bristol) said that pædiatricians desired to concentrate on problems of the newborn in maternity units with four main objects: (1) to acquire knowledge of function; (2) by the supervision and care of the newborn and control of the obstetric house-surgeon, to implement the new knowledge; (3) to detect the early signs of disease; and (4) the least important—to treat the sick baby. Should the need for treatment of the sick be common, the control of the pædiatrician had failed.

Mr. A. AMBERY SMITH (Leeds) described the effect of the pædiatrician taking charge of the baby at birth on the experience and training of the young obstetrician. Eight obstetricians trained at his hospital under this system were now consultants; and of these, six had charge in large areas where a pædiatrician was not available. There was also a serious gap in the training of house-surgeons proceeding to the diploma examination of the Royal College of Obstetricians and Gynæcologists before entering general practice.

Prof. G. GORDON LENNON (Bristol) said that obstetricians must bear the responsibility for neglect of baby-care in the past. Pædiatrics was a new specialty that, in the asphyxial stage some twenty to thirty years ago, had been treated by the obstetrician with a liberal supply of oxygen and left alone. As a child it had done as children did, when unchecked, and taken liberties. Now that it had become a man it should put away childish things. Its sphere of influence should be limited and defined. Antenatal pædiatrics was obstetrics. Why should the obstetrician hand over a baby for resuscitation to a houseman untrained in obstetrics? The consultant pædiatrician was never seen in the labour-room during the night. The specialty of obstetrics and gynæcology was being assailed on all sides—in this case by the pædiatrician, in other cases by the radiotherapeutist over the treatment of uterine cancer, by the radiologist indicating when to do a cæsarean section for disproportion, or by the midwife for the care of normal labour. The wealth of attraction of the specialty was becoming apparent to all. Obstetricians must protect their interests.

Prof. W. I. C. MORRIS (Manchester) was aware of friction arising over infrequent visits by the pædiatrician, the management of breast-feeding, and the methods of resuscitation of the newborn. It should be remembered that pædiatricians were too few to provide a complete service to specialist-staffed maternity hospitals, while many maternity units were staffed entirely by general practitioners. It was therefore still vitally necessary to train obstetric house-surgeons and registrars in neonatal pædiatrics. It was also highly desirable that trained obstetricians—both general practitioners and specialists—should have opportunities to refresh their pædiatric knowledge. In a fully staffed maternity unit, usually in a teaching hospital, some rules could be made with advantage, such as:

1. The obstetrician delegates labour-room duties only to a colleague of equivalent professional status.

2. The pædiatrician takes complete control of babies in wards or nurseries—and of breast-feeding of all lactating mothers.

3. The obstetrician resumes complete control of all mothers when the general physical or mental condition makes this desirable, as when fever occurs.

4. The obstetrical house-surgeons should be made responsible for some agreed portion of the pædiatric duties.

High standards of professional behaviour would ensure good relations between colleagues.

Stress Incontinence of Urine

Dr. **Albert H. Aldridge** (New York) discussed the conditions which may create an abnormally high intravesical pressure, including reflex irritability due to inflammatory lesions; and he does not regard leakage of urine from this cause through a normal urethra as true stress incontinence. Leakage of the stress type occurred in the presence of fairly gross anatomical changes involving the urethra and bladder and their supporting structures. From clinical experience and limited knowledge of the mechanism of control of micturition, it seemed important in surgical treatment to do three things: (1) to reduce the lumen of an overstretched urethra to normal and to restore the shortened urethral canal to its original length; (2) to repair the damaged, overstretched, and retracted urethral sphincter-muscles; and (3) to construct a support from the surrounding tissues to hold the urethra and vesical neck as high as possible in the pelvis. Care should be taken to exclude or discover and correct symptoms due to urge incontinence. In general, operations should not be undertaken until at least six months after the original injury or a previous operation for the same condition.

In Dr. Aldridge's experience vaginal operations of the type devised by Kelly (1911) cured about 80% of patients; and the modification introduced by Kennedy had somewhat improved the results. There remained some 10–20% of partial or complete surgical failures. In 1941 he treated a patient in whom leakage of urine had not been cured by three vaginal plastic operations. After another plastic operation by the Kennedy method and transplantation of fascia to form a supporting sling beneath the proximal end of the urethra, this patient had now been continent and free from bladder symptoms for more than ten years. Further experience had shown that this method was relatively simple and safe if dissections were carried out in natural planes of cleavage. The procedure might fail if the sling was not made sufficiently taut, if the abdominal wall was too relaxed, or if the urethra and vesical neck could not be freely mobilised on account of dense scar tissue.

Commenting on the Millin and Read report of only 1 known failure after 140 operations using a fascial sling by the suprapubic route, Dr. Aldridge said that the results were remarkable if the assumption was correct that many women in this series had vaginal birth injuries which were not repaired. Another suprapubic procedure which, used alone without attempt to repair birth injuries to the urethra and bladder, had produced good results was the Marshall and Marchetti operation, which pulled the urethra and bladder-wall forward and upward to be fixed to the pubic bone and anterior abdominal wall.

At a recent meeting of the New York Obstetrical Society, Ball, of Cornell, reported 94% cures from treatment of stress incontinence by combination of a vaginal plastic operation of the modified Kelly type, tightening of the vesical neck on its anterior surface, and fixation of the urethra and bladder-neck to the pubic bone and anterior abdominal wall.

Speculating on why sling operations or suprapubic fixation of the urethra and bladder will cure some women in whom plastic vaginal operations have failed, Dr. Aldridge said that it is apparent that to restore function of the urethral-sphincter mechanism the urethra and vesical neck must be supported high in the pelvis. The success of the Millin-Read sling technique and the Marshall-Marchetti vesico-urethral suspension operation as single procedures—that is, without a preliminary vaginal plastic operation—underlined the importance of this step in any surgical technique for relief of stress incontinence.

If Jeffcoate had found the explanation of the present vaginal plastic failures and the success of the suprapubic procedures, a satisfactory vaginal operation might eventually be found.

Professor **Jeffcoate** reported the results of cysto-urethrography in relation to stress incontinence. He showed the limitations of anteroposterior and oblique studies. By his lateral studies he had discerned important anatomical changes in 90% of cases. In a control group of nulliparous women, and in parous women without prolapse or incontinence, with the bladder full and the patient standing, the bladder-base normally lay parallel with, and 1–2 cm. above, a line joining the lower border of the symphysis pubis to the last piece of the sacrum. The urethra was straight and made a clearly defined and angled junction with the bladder. There was no suggestion of a "neck" to the bladder. The internal urethral meatus was 2–3 cm. away from the symphysis pubis. The posterior urethrovesical angle, which normally measured about 100°, was especially important. A strong bearing-down effort moved the bladder-base and upper urethra slightly downwards and backwards, this displacement being sometimes as much as 1 cm. in multiparous women. The angle and shape of the urethrovesical junction were unchanged by stress. During micturition the bladder became ovoid in shape; the bladder-base and the upper urethra moved downwards and backwards, but the lower urethra remained fixed at the level of the triangular ligament. As the movement exceeded that noted during stress, a relaxation of the pelvic-floor musculature was assumed to bring about this descent. Along with this movement the urethrovesical angle was obliterated, and both urethra and trigone were seen to lie in a straight line, the meatus and upper urethra becoming funnel-shaped, and the remainder of the urethra running straight to its lower fixed point where it was angled to take a downwards direction. The upper movable part of the urethra lay parallel to the plane of the pelvic brim.

In cases of stress incontinence the most striking and constant finding was loss of the normal urethrovesical angle, so that the base of the bladder and urethra were in line. In most this change was present at rest; in some it became apparent only on straining. Funnelling of the urethrovesical junction was seldom seen without a coincident change in the urethrovesical angle. Increased downward movement of the bladder-base, except as related to loss of angulation, was probably insignificant in that it appeared to be related to the degree of prolapse rather than to the severity of the incontinence. During micturition the appearances were essentially the same as in normal controls.

In cases with prolapse without loss of the posterior urethrovesical angle, incontinence was caused only when the trigone was involved. If cystocele involved the bladder-base behind Mercier's bar, incontinence did not result. From this evidence it might be concluded that any operation which was to cure stress incontinence must aim above all at restoring the urethrovesical angle and correcting any funnelling of the internal meatus, the former being the more important. This conclusion was strengthened, and the significance of the anatomical changes found in stress incontinence confirmed, by radiological examination of patients before and after operative treatment.

Dr. **Henry Roberts** (Liverpool) showed lateral cysto-urethrograms in 3 cases after successful Marshall-Marchetti operations which had restored the posterior urethrovesical angle. The inference was that continence depended on a satisfactory condition in the intrinsic musculature about the bladder-base and urethral junction, and not on the state of the pelvic-floor musculature and fasciæ.

Dr. **A. G. I. Ingelman-Sundberg** (Stockholm) and Mr. **J. H. Mulvaney** (Surrey) reported on their operations. Prof. **E. Bracht** (Berlin) showed a film of a new method of elevating the bladder-neck region. Dr. **John R. Upton** (San Francisco) described his adaptation of the Le Fort operation in the aged.

Several speakers referred to the need for care in diagnosing and selecting cases for operation, and for examination by the surgeon in assessing the late results of treatment. Mr. **W. R. Sloan** (Bangor, Northern Ireland) referred to difficulties and unsatisfactory results after sling operations. Professor **Lennon** had seen ill results from sling operations. He was now trying the Mulvaney operation, so far with promising effect. Mr. **J. A. Chalmers** (Worcester) was trying the Marshall-Marchetti operation, and had so far cured all but 1 of 30 cases.

Mr. **L. G. Phillips** (London) did not agree that the failure-rate with vaginal plastic operations was as high as others estimated, provided that the operator was experienced and he made a careful deliberate dissection. Prof. **Chassar Moir** agreed with Mr. Phillips. He referred to the merits of the Millin and Aldridge sling techniques in cases where the vaginal operation had failed. He preferred the Aldridge operation, although it took more time to perform and required two openings; there were few dangers, and the sling tension could be accurately adjusted. He gave a caution concerning the psychological element in assessing the patient before and after operation. In a follow-up, at least six months should have elapsed and the patient should be examined with her bladder full.

Genital Tuberculosis

Dr. **Magnus Haines** (London) believed that pelvic tuberculosis arose by blood-stream infection from extragenital foci. Many of his patients had earlier manifestations of tuberculosis, including pleurisy, cervical adenitis, iritis, peritonitis, and pulmonary, renal, and bone infections. He questioned the belief of some physicians that genital lesions were uncommon among sanatorium patients, and cited Jedburgh's finding on menstrual culture of 5 women with latent genital lesions among 100 sanatorium patients. There was also ample evidence of genital tuberculosis in 7–8% of women who died of pulmonary tuberculosis.

Concerning morbid anatomy, in some cases the uterus, fallopian tubes, and ovaries might appear normal on naked-eye examination. In addition to the exudative and adhesive types of tubal disease, both hæmatosalpinx and hydrosalpinx might be tuberculous. The ovaries were involved in about a quarter of the cases. In early cases the endometrium might look normal. When involved, the myometrium was invaded from the endometrium. The diagnosis by histology had so many limitations that investigators required to find the tubercle bacillus for confirmation. A small portion of suspected tissue might be implanted in the thigh muscles of the guineapig; the organisms obtained might then be used for sensitivity tests with antibiotics and for typing of strain. He believed that nearly always female genital tuberculosis was due to a human-type bacillus.

Mr. **John Stallworthy** (Oxford) dealt with clinical features in his 78 proven cases. The only patient who died was an infertile woman with unsuspected endometrial disease who refused treatment and died one year later of miliary tuberculosis. He believed that there were more women with unsuspected tuberculous pelvic disease than there were with symptoms or signs. Infertility was a complaint in more than half his cases: there were associated gynæcological symptoms in one-fifth of these. Menstruation was normal in half his patients; menorrhagia occurred inconstantly in some, but amenorrhœa was rare. This emphasised the importance of endometrial studies before initiating hormone therapy for menstrual disorders. Pain was not usually prominent. Peritonitis might heal, leaving tubal function unimpaired; and in 1 case pregnancy followed. Deterioration was usually insidious, and ascites might develop with other pelvic signs. Fistulæ might complicate extensive pelvic disease or follow imperfect surgery.

In treatment striking success followed painstaking preparation followed by total hysterectomy and excision of fistulous tracts and diseased bowel; in some instances such success was obtained before the introduction of streptomycin. By contrast, a patient with a unilateral pyosalpinx, colovesical fistula, large posterior myoma, and heavily infected bladder and endometrium was treated with streptomycin 1 g. daily for three months; the tuberculous infection was clinically cured, but the fistula persisted. The patient was anxious to avoid hysterectomy. The affected colon was excised, a myomectomy performed, and the uterine hood used to extraperitonealise the indurated bladder fistula. At eighteen months the patient was well.

Mr. **A. M. Sutherland** (Glasgow) reported on 46 patients receiving 1 g. of streptomycin daily, and 3 g. of P.A.S. four times daily, for eighty-four days, and 29 patients observed as a control group. These 75 patients had histologically proved disease. The endometrium had remained positive in most of the control group. Of the control patients, 1 was later found to have a tuberculous infection of the urinary tract, a 2nd was subsequently brought under treatment because of clinical deterioration, and a 3rd failed to report regularly and now had tuberculous meningitis. Among the treated patients no permanent ill effects had been noted. Treatment was discontinued for slight vestibular disturbances in 2 patients at 52 and 27 g. streptomycin; and a third patient had treatment discontinued at 22 g. because of skin eruption and hair loss. One patient with disease apparently limited to the cervix was six months negative to biopsy test. 3 patients developed peritonitis after the original diagnostic procedures. This complication rapidly subsided with commencement of treatment; repeat biopsies had, however, been omitted. In the remaining 39 cases, premenstrual endometrial biopsies were performed half-way through treatment, at the end of treatment, after three and six months, and at the end of a year, with guineapig inoculation. So far the endometrium had remained negative in most of the treated cases.

Mr. **Linton Snaith** (Newcastle upon Tyne) presented evidence that genital tuberculosis should be regarded as one of the earliest postprimary infections occurring within three years of effective exposure to the disease, judged by the appearance of an obvious primary manifestation such as erythema nodosum. If the primary infection occurred in childhood, when the genital tract was inactive, this escaped infection, resistance was established, and the genital tract rarely suffered. With adolescence the genital tract was active and vulnerable, and school-leaving increased the risk of exposure to infection.

Dr. E. **Rabau** (Israel) reported the treatment of a *bacteriologically proved case of genital tuberculosis* by streptomycin 100 g., followed by insufflation. In this case there was subsequently a successful pregnancy.

The transactions of the congress will be published in the *Journal of Obstetrics and Gynæcology.*

UNIVERSITY COLLEGE HOSPITAL, LONDON

It has long been the custom for the aged sick to be cared for in hospitals which cater chiefly for chronic illness. This association has led to the belief that any old person who falls ill will need a long stay in hospital. As a result, in the present scarcity of hospital beds, it has become increasingly difficult to obtain admission for old people even when they are suffering from acute illness.

While we recognise that a small proportion of elderly sick will require a long stay in hospital (often for social rather than medical reasons), this is not true of the majority, as will be seen from our analysis of a year's admissions at University College Hospital.

A YEAR'S EXPERIENCE

The hospital's unit for the care of the aged sick has been described already (Exton-Smith and Crockett 1949, Amulree et al. 1951). There are now 120 hospital beds and a further 30 in a hostel (the Barlow Home) which serves in part as a "half-way house" and in part, inadvertently, as a long-stay annexe. We still have 45 patients who were in the hospital when it was taken over from the London County Council in July, 1948; a further 32 beds are blocked by patients admitted since July, 1948, who have been in hospital for over six months. Of these 77 long-stay patients, 23 are in the Barlow Home.

Most patients admitted come from the borough of St. Pancras, requests being received from general practitioners and also through the Emergency Bed Service. Nearly all of them are first seen by one of us in their own homes to assess their claim to priority of admission.

A great variety of diseases has been treated; cerebral vascular lesions and cardiac and chest conditions were the most common. There were several patients with skin disorders and a few with *pulmonary tuberculosis*. Nearly all were over 65 years old; the average age of the men was $74^1/_4$ years and of the women $76^1/_2$ years.

RESULTS

During the year from July 1, 1950, to June 30, 1951, 340 patients (180 men and 160 women) were admitted; of this total, 40 (11·8%) remained in hospital for more than 6 months and are regarded as long-stay patients. The average stay in hospital of the remaining 300 was 40·2 days; any part of a patient's stay which was in the Barlow Home is included as part of the stay in hospital (see table).

PATIENTS ADMITTED TO THE GERIATRIC UNIT 1950–51

—	Remained in hospital over 6 months	Stayed less than 6 months			Average length of stay in days of groups a, b, and c	Average age in years
		(*a*) Died	(*b*) Discharged	(*c*) * Transferred		
Males (180)	17	54	90	19	38·9	$74^1/_4$
Females (160)	23	51	79	7	41·6	$76^1/_4$
Totals (340)	40 (*11·8%*)	105 (*30·9%*)	169 (*49·7%*)	26 (*7·6%*)	40·2	...

* Some of these patients were transferred for surgical treatment. Others showed mental changes with antisocial habits which made it difficult to nurse them in a general ward; they were not certified, but, after a period of observation, went to hospitals provided for such cases.

The average length of stay of adult patients admitted to the medical wards of University College Hospital during the year 1950 was 35·1 days. When those with tuberculosis and skin diseases were excluded the average length of stay was reduced to 32·6 days.

DISCUSSION

Our survey thus shows that the stay in this hospital of the great majority of elderly sick is not much longer than that of younger medical patients. Many of our acute cases were accepted after the Emergency Bed Service had failed to get them into other hospitals. Our experience suggests that admission officers are often unduly apprehensive of having their beds blocked by old people. Graham (1951) gained the same impression from a study of elderly patients referred to the Emergency Bed Service.

We have not confined our patients for admission to those whose prognosis seemed relatively good; even those with obviously terminal diseases were not rejected. Thus the number of deaths, most of which occurred within a month of admission, is high—105 (or 30·9%).

We do not yet know how long those patients who remained in hospital for over 6 months are likely to stay; of the 40 such patients admitted in the year ended on June 30, 1951, 16 were still in hospital on May 31, 1952.

SUMMARY

Of 340 elderly patients admitted to this unit during one year, 300 stayed in hospital for less than 6 months. The average length of stay of these 300 patients was 40·2 days.

The average length of stay of adult medical patients in the wards of the rest of University College hospital was 35·1 days.

When admitted to hospital, the great majority of elderly sick occupy a bed little longer than do younger patients.

We wish to thank Miss A. Cocks of the secretarial staff for her help in the preparation of our figures and Mr. D. M. Iles, the records officer, for providing the figures for the general medical wards.

rather than to the severity of the incontinence. During micturition the appearances were essentially the same as in normal controls.

In cases with prolapse without loss of the posterior urethrovesical angle, incontinence was caused only when the trigone was involved. If cystocele involved the bladder-base behind Mercier's bar, incontinence did not result. From this evidence it might be concluded that any operation which was to cure stress incontinence must aim above all at restoring the urethrovesical angle and correcting any funnelling of the internal meatus, the former being the more important. This conclusion was strengthened, and the significance of the anatomical changes found in stress incontinence confirmed, by radiological examination of patients before and after operative treatment.

Dr. HENRY ROBERTS (Liverpool) showed lateral cysto-urethrograms in 3 cases after successful Marshall-Marchetti operations which had restored the posterior urethrovesical angle. The inference was that continence depended on a satisfactory condition in the intrinsic musculature about the bladder-base and urethral junction, and not on the state of the pelvic-floor musculature and fasciæ.

Dr. A. G. I. INGELMAN-SUNDBERG (Stockholm) and Mr. J. H. MULVANEY (Surrey) reported on their operations. Prof. E. BRACHT (Berlin) showed a film of a new method of elevating the bladder-neck region. Dr. JOHN R. UPTON (San Francisco) described his adaptation of the Le Fort operation in the aged.

Several speakers referred to the need for care in diagnosing and selecting cases for operation, and for examination by the surgeon in assessing the late results of treatment. Mr. W. R. SLOAN (Bangor, Northern Ireland) referred to difficulties and unsatisfactory results after sling operations. Professor LENNON had seen ill results from sling operations. He was now trying the Mulvaney operation, so far with promising effect. Mr. J. A. CHALMERS (Worcester) was trying the Marshall-Marchetti operation, and had so far cured all but 1 of 30 cases.

Mr. L. G. PHILLIPS (London) did not agree that the failure-rate with vaginal plastic operations was as high as others estimated, provided that the operator was experienced and he made a careful deliberate dissection. Prof. CHASSAR MOIR agreed with Mr. Phillips. He referred to the merits of the Millin and Aldridge sling techniques in cases where the vaginal operation had failed. He preferred the Aldridge operation, although it took more time to perform and required two openings; there were few dangers, and the sling tension could be accurately adjusted. He gave a caution concerning the psychological element in assessing the patient before and after operation. In a follow-up, at least six months should have elapsed and the patient should be examined with her bladder full.

Genital Tuberculosis

Dr. MAGNUS HAINES (London) believed that pelvic tuberculosis arose by blood-stream infection from extragenital foci. Many of his patients had earlier manifestations of tuberculosis, including pleurisy, cervical adenitis, iritis, peritonitis, and pulmonary, renal, and bone infections. He questioned the belief of some physicians that genital lesions were uncommon among sanatorium patients, and cited Jedburgh's finding on menstrual culture of 5 women with latent genital lesions among 100 sanatorium patients. There was also ample evidence of genital tuberculosis in 7–8% of women who died of pulmonary tuberculosis.

Concerning morbid anatomy, in some cases the uterus, fallopian tubes, and ovaries might appear normal on naked-eye examination. In addition to the exudative and adhesive types of tubal disease both hæmatosalpinx and hydrosalpinx might be tuberculous. The ovaries were involved in about a quarter of the cases. In early cases the endometrium might look normal. When involved, the myometrium was invaded from the endometrium. The diagnosis by histology had so many limitations that investigators required to find the tubercle bacillus for confirmation. A small portion of suspected tissue might be implanted in the thigh muscles of the guineapig; the organisms obtained might then be used for sensitivity tests with antibiotics and for typing of strain. He believed that nearly always female genital tuberculosis was due to a human-type bacillus.

Mr. JOHN STALLWORTHY (Oxford) dealt with clinical features in his 78 proven cases. The only patient who died was an infertile woman with unsuspected endometrial disease who refused treatment and died one year later of miliary tuberculosis. He believed that there were more women with unsuspected tuberculous pelvic disease than there were with symptoms or signs. Infertility was a complaint in more than half his cases; there were associated gynæcological symptoms in one-fifth of these. Menstruation was normal in half his patients; menorrhagia occurred inconstantly in some, but amenorrhœa was rare. This emphasised the importance of endometrial studies before initiating hormone therapy for menstrual disorders. Pain was not usually prominent. Peritonitis might heal, leaving tubal function unimpaired; and in 1 case pregnancy followed. Deterioration was usually insidious, and ascites might develop with other pelvic signs. Fistulæ might complicate extensive pelvic disease or follow imperfect surgery.

In treatment striking success followed painstaking preparation followed by total hysterectomy and excision of fistulous tracts and diseased bowel; in some instances such success was obtained before the introduction of streptomycin. By contrast, a patient with a unilateral pyosalpinx, colovesical fistula, large posterior myoma, and heavily infected bladder and endometrium was treated with streptomycin 1 g. daily for three months; the tuberculous infection was clinically cured, but the fistula persisted. The patient was anxious to avoid hysterectomy. The affected colon was excised, a myomectomy performed, and the uterine hood used to extraperitonealise the indurated bladder fistula. At eighteen months the patient was well.

Mr. A. M. SUTHERLAND (Glasgow) reported on 46 patients receiving 1 g. of streptomycin daily, and 3 g. of P.A.S. four times daily, for eighty-four days, and 29 patients observed as a control group. These 75 patients had histologically proved disease. The endometrium had remained positive in most of the control group. Of the control patients, 1 was later found to have a tuberculous infection of the urinary tract, a 2nd was subsequently brought under treatment because of clinical deterioration, and a 3rd failed to report regularly and now had tuberculous meningitis. Among the treated patients no permanent ill effects had been noted. Treatment was discontinued for slight vestibular disturbances in 2 patients at 52 and 27 g. streptomycin; and a third patient had treatment discontinued at 22 g. because of skin eruption and hair loss. One patient with disease apparently limited to the cervix was six months negative to biopsy test. 3 patients developed peritonitis after the original diagnostic procedures. This complication rapidly subsided with commencement of treatment; repeat biopsies had, however, been omitted. In the remaining 39 cases, premenstrual endometrial biopsies were performed half-way through treatment, at the end of treatment, after three and six months, and at the end of a year, with guineapig inoculation. So far the endometrium had remained negative in most of the treated cases.

Mr. LINTON SNAITH (Newcastle upon Tyne) presented evidence that genital tuberculosis should be regarded as one of the earliest postprimary infections occurring within three years of effective exposure to the disease, judged by the appearance of an obvious primary manifestation such as erythema nodosum. If the primary infection occurred in childhood, when the genital tract was inactive, this escaped infection, resistance was established, and the genital tract rarely suffered. With adolescence the genital tract was active and vulnerable, and school-leaving increased the risk of exposure to infection.

Dr. E. RABAU (Israel) reported the treatment of a bacteriologically proved case of genital tuberculosis by streptomycin 100 g., followed by insufflation. In this case there was subsequently a successful pregnancy.

The transactions of the congress will be published in the *Journal of Obstetrics and Gynæcology.*

UNIVERSITY COLLEGE HOSPITAL, LONDON

IT has long been the custom for the aged sick to be cared for in hospitals which cater chiefly for chronic illness. This association has led to the belief that any old person who falls ill will need a long stay in hospital. As a result, in the present scarcity of hospital beds, it has become increasingly difficult to obtain admission for old people even when they are suffering from acute illness.

While we recognise that a small proportion of elderly sick will require a long stay in hospital (often for social rather than medical reasons), this is not true of the majority, as will be seen from our analysis of a year's admissions at University College Hospital.

A YEAR'S EXPERIENCE

The hospital's unit for the care of the aged sick has been described already (Exton-Smith and Crockett 1949, Amulree et al. 1951). There are now 120 hospital beds and a further 30 in a hostel (the Barlow Home) which serves in part as a "half-way house" and in part, inadvertently, as a long-stay annexe. We still have 45 patients who were in the hospital when it was taken over from the London County Council in July, 1948; a further 32 beds are blocked by patients admitted since July, 1948, who have been in hospital for over six months. Of these 77 long-stay patients, 23 are in the Barlow Home.

Most patients admitted come from the borough of St. Pancras, requests being received from general practitioners and also through the Emergency Bed Service. Nearly all of them are first seen by one of us in their own homes to assess their claim to priority of admission.

A great variety of diseases has been treated; cerebral vascular lesions and cardiac and chest conditions were the most common. There were several patients with skin disorders and a few with pulmonary tuberculosis. Nearly all were over 65 years old; the average age of the men was 74¼ years and of the women 76½ years.

RESULTS

During the year from July 1, 1950, to June 30, 1951, 340 patients (180 men and 160 women) were admitted; of this total, 40 (11·8%) remained in hospital for more than 6 months and are regarded as long-stay patients. The average stay in hospital of the remaining 300 was 40·2 days; any part of a patient's stay which was in the Barlow Home is included as part of the stay in hospital (see table).

PATIENTS ADMITTED TO THE GERIATRIC UNIT 1950–51

—	Remained in hospital over 6 months	Stayed less than 6 months			Average length of stay in days of groups a, b, and c	Average age in years
		(a) Died	(b) Discharged	(c) *Transferred		
Males (180)	17	54	90	19	38·9	74¼
Females (160)	23	51	79	7	41·6	76½
Totals (340)	40 (11·8%)	105 (30·9%)	169 (49·7%)	26 (7·6%)	40·2	..

* Some of these patients were transferred for surgical treatment. Others showed mental changes with antisocial habits which made it difficult to nurse them in a general ward; they were not certified, but, after a period of observation, went to hospitals provided for such cases.

The average length of stay of adult patients admitted to the medical wards of University College Hospital during the year 1950 was 35·1 days. When those with tuberculosis and skin diseases were excluded the average length of stay was reduced to 32·6 days.

DISCUSSION

Our survey thus shows that the stay in this hospital of the great majority of elderly sick is not much longer than that of younger medical patients. Many of our acute cases were accepted after the Emergency Bed Service had failed to get them into other hospitals. Our experience suggests that admission officers are often unduly apprehensive of having their beds blocked by old people. Graham (1951) gained the same impression from a study of elderly patients referred to the Emergency Bed Service.

We have not confined our patients for admission to those whose prognosis seemed relatively good; even those with obviously terminal diseases were not rejected. Thus the number of deaths, most of which occurred within a month of admission, is high—105 (or 30·9%).

We do not yet know how long those patients who remained in hospital for over 6 months are likely to stay; of the 40 such patients admitted in the year ended on June 30, 1951, 16 were still in hospital on May 31, 1952.

SUMMARY

Of 340 elderly patients admitted to this unit during one year, 300 stayed in hospital for less than 6 months. The average length of stay of these 300 patients was 40·2 days.

The average length of stay of adult medical patients in the wards of the rest of University College hospital was 35·1 days.

When admitted to hospital, the great majority of elderly sick occupy a bed little longer than do younger patients.

We wish to thank Miss A. Cocks of the secretarial staff for her help in the preparation of our figures and Mr. D. M. Iles, the records officer, for providing the figures for the general medical wards.

Parliament

W.H.O. and Population Problems

In the debate on the adjournment on July 18, Mr. DOUGLAS HOUGHTON recalled recent discussions at the World Health Assembly, on the Norwegian proposal to set up an expert committee "to examine and report on the health aspects" of the population problem. The resolution was opposed by delegations from Catholic countries on the grounds that if the committee recommended that birth-control were included in the permanent programme of W.H.O., that body might lose not only good will but some members. Eventually the Norwegian resolution was withdrawn. As the United Kingdom delegate, Dr. Mackenzie, did not state what our Government's policy was in this matter Mr. Houghton asked the parliamentary secretary to do so. He admitted that the problem of population had not only health, moral, and social aspects, but also sectarian aspects. But, while we must respect religious opinion that did not mean we must submit to it. He believed that disease, misery, death, and starvation were infinitely more immoral than any form of birth-control.

Miss PATRICIA HORNSBY-SMITH said that from the outset it had been the policy of the World Health Assembly and W.H.O. that birth-control was primarily a sociological and not a medical question and that W.H.O. would be competent to advise only in the medical aspect. It was felt that to introduce the economic or sociological side would do grave harm to a new organisation which had an immense field of work in health welfare which it was doing in the most coöperative spirit. An enormous amount of good was being done in fighting disease throughout the world; and if a matter as violently controversial as this topic were brought into this organisation, it would mean the secession of several of the nations who now worked in coöperation with us.

The subject was first introduced at the conference in May, 1952, by the Food and Agriculture Organisation representative, who pointed out the difficulty of feeding the growing populations of the world. The Indian delegate then reported on the experiment in the "rhythm" method of birth-control, in which W.H.O. had collaborated, and was still collaborating, at the request of the Indian government, giving purely medical guidance. The request for that guidance was conditional upon the experiments being restricted to the use of the "safe period," and without the use of mechanical contrivances. The Norwegian delegate's resolution was supported by some delegations, and was strenuously opposed by a substantial team of delegates who held opposing views. One of the reasons against it was that if such an expert committee produced a report it would undoubtedly be taken as the policy of W.H.O. To avoid controversy the Indian delegate put in an alternative resolution which was followed by one from Belgium, the Lebanon, and Italy. Finally, after heated discussions, only palely reflected in the brief official minutes, with agreement all round and a realisation that W.H.O. was too big to split on this topic at this time the motions were all withdrawn.

Replying to the charges that the United Kingdom delegate took no part in the debate, Miss Hornsby-Smith affirmed that his position was clear. The British Government did not believe that it was any part of the duty of W.H.O. to interfere with, or impose, policy on economic grounds. That was the concern of the individual sovereign governments. The representative of H.M. Government did not enter into the discussion at the conference because he felt it ranged far beyond what he thought could be introduced by W.H.O. We had great responsibilities of our own towards native populations under our jurisdiction, and the Government had set themselves against imposing anything of this nature on any territory under our control. Such a policy could readily be misrepresented as an attempt to control native populations to the advantage of white minorities. In short, she affirmed, the Government did not consider that W.H.O. is competent to discuss or express views on the social, economic, or ethical aspects of birth-control.

Medical Problems of Civil Defence

Speaking in the debate on civil defence in the House of Commons on July 18, Dr. BARNETT STROSS pointed out that methods and techniques of civil defence had changed since the late war. The four things to guard against, he said, were high explosives—now an old-fashioned weapon—fire bombs, particularly of the napalm type—atom bombs, and disease attacks. He did not think the latter would in fact be used, for there was no highly technically evolved people that would not be prepared and able to answer back in a like way. Statements, such as that made by General Alden H. Waitt, chief of the United States Army Chemical Corps, who said

> "Clostridium botulinum is the most poisonous thing known to man, and under ideal conditions one ounce would probably kill 150 million people."

did not mean much, because those conditions did not obtain.

Fire bombs and atom bombs were a different matter, and in his view the essential problem of civil defence, was the treatment of burns. Blood plasma and blood would be needed in huge amounts, and he asked the Home Secretary to what extent these were being stockpiled. In the first three or four days anyone suffering from burns—with a skin area up to 50% involved—would need 20 to 30 pints. After that, if the patient survived he would need the usual 20 to 30 operations over a period of two years. What steps were the Government taking to increase the numbers of skilled medical personnel, plus ancillary services for skin grafting and plastic surgery? There were centres in Birmingham and Glasgow, but he doubted whether there were more than two really efficient teams. If they were working all out probably they could not handle more than three or four cases an hour. If there were 20,000 or 30,000 casualties in one incident—which happened at Hamburg without atomic bombs—this country would need to be much better prepared than it was. At Hiroshima there were 34,000 cases of burns. Besides blood and blood plasma we should need stocks of antibiotics and dressings. If this problem was to be tackled seriously a fairly high but elementary level of training was needed throughout the whole population and in addition a large number of highly and technically trained personnel.

Sir DAVID MAXWELL FYFE, the Home Secretary, said he would see that the suggestions underlying Dr. Stross's questions were carefully studied. The question of stocks of blood was in hand at the Ministry of Health. The Government, he continued, did not believe that the atom bomb had made all civil defence useless, but that did not mean that they underestimated its potentialities. At the same time, the danger of lingering radioactivity had been exaggerated. Except in the area immediately below the burst of the bomb, which would be devastated, the probability of radioactive contamination persisting over any appreciable area for more than a short time would be exceedingly remote. The immediate radioactive effects of an atomic explosion did create a new problem, but the Government did not believe that it was insoluble. A great deal of preliminary planning had been done against the danger of fire—for example, in designing new types of emergency fire appliances and equipment.

Of the 263,458 recruits who had been enrolled for civil defence 25,000 were in the National Hospital Service Reserve. The responsibility for the enrolment and training of auxiliary members of the National Hospital Service Reserve, Sir David continued, had been accepted by the British Red Cross Society and the St. Andrew's Ambulance Association.

QUESTION TIME

Preregistration Period for Doctors

In answer to a question, Mr. IAIN MACLEOD, the Minister of Health, stated that he was informing hospital authorities that the General Medical Council have prescribed a year as the requisite period of employment in an approved hospital or approved institution following the passing of a qualifying examination before a person can be registered under the Medical Acts, and that the necessary draft Order will be laid before Parliament. The new provision would come into operation on Jan. 1, 1953, and the necessary formal draft Order in Council had been submitted for the approval of the Privy Council. He would be issuing a circular to hospital authorities giving guidance on the action to be taken by them.

Trainee Scheme in General Practice

Replying to a question, Mr. MACLEOD, said that no changes were at present under consideration in the trainee scheme for general practitioners. During the quarter ending March 31, 1952, 363 doctors in England and Wales were receiving a training grant, and in the quarter ending March 31, 1951, the number was 359.

Mental Hospital Staff

Replying to a question on the shortage of nursing staff at mental hospitals, Mr. MACLEOD said that during the past year there had been a slight rise in the number of women nurses, but on the men's side the position had worsened. The present shortage was about 3400 men and 7800 women.

R.H.B. Area Committees

Major E. G. R. LLOYD asked the Minister how many of the regional hospital boards, because their regions are too large for effective administration, were working through a number of area committees.—Mr. MACLEOD replied: One board has appointed area committees for the whole region and three for a part of their region. The functions of these committees vary widely, and not all have executive powers.

Military Hospital Services

Replying to questions on the treatment of British troops wounded in Korea, military hospital buildings and services in general with a view to improvements, Mr. ANTHONY HEAD, Secretary of State for War, said that the Commonwealth Division had the normal three field ambulances and one field dressing station for light cases. Casualties were then evacuated to a mobile Army surgical hospital. Thence, when fit to travel, they went by air to the 29th British General Hospital in Japan. From there, serious cases were brought to this country by air, while the remainder passed to a convalescent training depot before returning to duty. He was well aware that much work was needed on hospital buildings but there were many civil and other military claims on the limited resources. The main problem in the hospital services was the recruitment of sufficient regular R.A.M.C. officers, and he was examining this question.

Quality of Milk

Replying to Mr. N. N. DODDS, who asked whether the Minister of Food was aware of the spate of protests by local authorities about the deterioration of the quality of milk, Major GWILYM LLOYD GEORGE said that the standards governing the composition of milk and its cleanliness and safety were laid down in statutory regulations administered by local authorities. The Ministry of Food were also empowered to specify areas in which only milk of special designation might be retailed and they were doing so as quickly as conditions permitted. The minimum standard was not too low; the average fat content throughout the country was above what was laid down by Statute.

Mr. P. L. E. SHURMER: Is the Minister aware that the city analyst of Birmingham recently stated that the milk standard was deteriorating fast and that there should be a standard below which no milk should be sold. Major LLOYD GEORGE: Birmingham is one of the cities which I hope will shortly be among the areas in which only the specially designated milk can be sold.

Poisons Board

In answer to a question Sir DAVID MAXWELL FYFE, Home Secretary, stated that the members of the Poisons Board and the authorities appointing them were as follows:

Bertram Reece (chairman), Metropolitan magistrate, J. M. Barnes, M.B., F. R. Thornton, H.M. Chief Inspector under the Dangerous Drugs Act, 1951, and R. A. E. Galley, PH.D. (Secretary of State for the Home Department); J. M. Johnston, F.R.C.S. (Secretary of State for Scotland); W. P. Kennedy, F.R.F.P.S., and Mrs. J. A. Hauff, assistant secretary, Ministry of Health (Minister of Health); C. T. Gimingham, F.R.I.C. (Minister of Agriculture and Fisheries); J. R. Nicholls, D.SC. (Government Chemist); B. A. Bull, PH.C., W. S. Howells, M.P.S., H. N [illegible] plethorpe, PH.C., and H. Noble, PH.C. [illegible] Britain); C. A. Keele, F.R.C.P. (R [illegible] London); Prof. D. M. Lyon, F.R. [illegible] sicians of Edinburgh); Prof. David [illegible] Council); G. Roche Lynch, M.B. ([illegible] of Great Britain and Ireland); F. ([illegible] ciation).

Public Health

The Nation's Health in 1950

THE Ministry of Health's annual report is an account to Parliament and people of work undertaken on their behalf and at their expense; and the sum of these reports down the years illuminates our medical and social progress. The report should also, however, focus attention on outstanding problems; and if it is to succeed here it must appear without undue delay. The broad problems outlined year by year seldom change quickly; but the reader of a delayed report is apt to forget this, and to regard the difficulties of two years ago as lightly as yesterday's toothache.

Sir John Charles, the chief medical officer, is evidently alive to this; for his report on the year 1950 [1] appears more than a month ahead of last year's publication date. We hope that, with the help of the Registrar-General and the Stationery Office, he can take a further month off in each of the next few years.

Part 1 of the report, dealing with the National Health Service, has not yet been issued.

TUBERCULOSIS

Sir John observes that "the remarkable fall of 20 per cent in the number of deaths from tuberculosis from the number in 1949, which was the lowest then recorded in this country, should greatly encourage us." In a chapter on the disease Dr. Norman Smith points out that the death-rate from this cause in 1950 was 364 per 1,000,000 population, compared with about 3456 in the 1850's.

The report pleads for coöperation between medical officer of health, chest physician, sanitary inspector, disablement rehabilitation officer, health visitor, home nurse, and home-help organiser. "In certain areas these people meet regularly to discuss problem cases and to agree action thereon. This plan might well be imitated by every local health authority in the country."

Since July 5, 1948, more than 3500 tuberculosis beds had been added in England and Wales: and during the year tuberculosis nurses increased by 700 whole-time and 150 part-time.

The position with regard to notifications was less satisfactory. Of deaths from tuberculosis, one in six was of a patient not notified before death; and in 1949 one local health authority recorded a proportion as high as one in three. In 1950 the notification-rate was about 1 per 1000 of the population.

During the year the number of mass miniature radiography units rose by 10 to 53. Of the $5^3/_4$ million people examined since the service was started in 1943, 94·6% were found to have no abnormal chest condition. Previously unsuspected active tuberculosis of the lungs was revealed in 3·7 per 1000.

There is a mistaken impression, says the report, that mass miniature radiography is standing still. Technique is in fact continually improving, and it is only a question of time—and a relatively short time—before mass miniature pictures will become as reliable as full-size pictures.

SOME OTHER NOTIFIABLE DISEASES

Smallpox.—The infant vaccination "acceptance-rate," based on births in the twelve months ended June 30, 1950, was 23·8%. This confirms the earlier impression that the popularity of routine vaccination of infants has declined since the repeal of the Vaccination Acts in 1948; but an increase in the number of primary vaccinations in the combined age-groups under 1 and 1–4 years suggests that the age at vaccination is tending to rise. Substantially less than one-tenth of the school-children primarily vaccinated as infants are now being revaccinated before they reach the age of 15.

Since 1948 complications of vaccination done under National Health Service arrangements have been reported to the Ministry. The complications thus reported in 1950 were: generalised vaccinia 15; postvaccinal encephalomyelitis 4 (none fatal); and 1 death, which was of a 67-year-old man.

---

[1] Report of the Ministry of Health; Part 2: On the State of the Public Health, being the annual report of the chief medical officer for the year 1950. Cmd. 8582. H.M. Stationery Office. Pp. 192. 6s.

On the 10th day after successful revaccination the vaccination area became much inflamed; the patient had severe constitutional disturbance with delirium; he became stuporose and incontinent, and died five days later. Necropsy showed purulent bronchitis, chronic bronchiectasis, and changes in the brain suggesting cerebral thrombosis; there was no histological evidence of encephalitis.

Diphtheria.—Notified cases amounted to 962 (1881 in 1949), and deaths 49 (84); and the case-fatality rate was 5·1 (4·5).

Immunisations numbered 517,436, compared with 693,441 in the previous year.

Scarlet Fever.—Deaths from scarlet fever numbered 33 (27 in 1949), and from streptococcal sore throat 61.

Poliomyelitis and Polioencephalitis.—During the year there were 7750 cases with 755 deaths. Notifications approached, and deaths exceeded, those in 1947, the year with the highest incidence recorded. In urban outbreaks the links in the chain of spread are obscured by the complexity of city life. Elsewhere, however, several outbreaks suggested a "chain" spread of infection which seems more or less typical of poliomyelitis in rural or semirural communities.

> "These rural outbreaks seem to give an impression that the infection at first moves through a relatively narrow stream of the population. If this were so it would seem difficult to reconcile it with the normally accepted view, based on certain immunological findings, that the virus of poliomyelitis is widespread, or well nigh ubiquitous, in the community. If the virus be virtually everywhere, there seems little hope of preventing infection, but if its distribution were limited to the patients and their contacts, its spread might perhaps be restricted to some extent by the available methods of prevention."

Dysentery.—Corrected notifications numbered 17,274—the highest total yet recorded. In 1949 the number was 4519. Much of the great increase was due to a greater prevalence in many parts of *Shigella sonnei.*

Food-poisoning.—Notified cases numbered 7506, but from special reports received from medical officers of health there was evidence that more than 17,000 people were affected. 64 deaths, 55 of which were due to salmonella infections, were reported. The foods proved, or thought most likely, to have been responsible for the spread of infection were noted in 435 outbreaks and family outbreaks. Of outbreaks in which the food responsible was known, 48% were due to processed and made-up meat dishes. An investigation of places where infection occurred suggested that "there is no reason to suppose that food poisoning arises less often in restaurants than in canteens."

MALARIA

The country remained entirely free of indigenous malaria. A survey at London Airport indicated that the risk of mosquitoes being introduced from the tropics is negligible, provided that aircraft are regularly sprayed.

VENEREAL DISEASE

The number of patients with syphilis attending clinics for the first time fell from 6812 in 1949 to 4143 in 1950. New cases of gonorrhœa decreased from 24,487 in 1949 to 20,504 in 1950.

COMMON COLD

An investigation in a Wiltshire village by the Common Cold Research Unit showed that school-children experienced about three times as many colds as adults living in households without school-children. The presence of school-children in the household approximately doubled the number of colds caught by both adults, and infants under 5 years of age. The risk of infection by exposure to another infected individual in the same household appeared to be about one in five.

Poliomyelitis

Total notifications of poliomyelitis in England and Wales up to and including the week ended July 12 were 1013. This compares with figures for the corresponding period in the last 5 years as follows:

1947	612
1948	746
1949	748
1950	1659
1951	1027

Weekly notifications from the week ended May 3 have been:

Week ended	*Paralytic*	*Non-paralytic*	*Total*
May 3..	15	9	24
,, 10..	15	6	21
,, 17..	25	12	37
,, 24..	18	19	37
,, 31..	26	18	44
June 7..	41	19	60
,, 14..	28	20	48
,, 21..	49	19	68
,, 28..	58	32	90
July 5..	61	25	86
,, 12..	78	41	119

Notifications (119) for the week ending July 12 were similar to those for the corresponding weeks in 1951 (120), 1949 (117), and 1947 (126). In 1950 the figures for the corresponding week were very much larger (212), and in 1948 considerably lower (38). Since the week ended May 31 inclusive, there have been 108 notifications from County Durham, a considerably higher figure than elsewhere. This total included 48 from Gateshead county borough and 19 from Felling urban district council. Counties with the next largest totals for the same period were: London (43), Northumberland (36), Middlesex (32), Warwick (32), and Lancashire (27).

It is difficult to draw any definite conclusion from these figures as to whether poliomyelitis is likely to become unusually epidemic this year. It is, however, clear that a significant increase in the numbers of notifications is taking place.

Dr. James Grant, medical officer of health for Gateshead writes:

> "Poliomyelitis has been prevalent on Tyneside, particularly on the south bank of the river, since May 3. Up to July 19, 93 cases had been confirmed, 62 in Gateshead county borough, 21 in Felling urban district, 9 in Whickham urban district, and 1 in Hebburn urban district. Prevalence has steadily increased, and reached a maximum last week with 17 confirmed cases on South Tyneside. North of the Tyne prevalence has been very slight.
>
> "The age-distribution of the South Tyneside cases is that of classical infantile paralysis; 64 were under the age of 5, 20 aged 5–9, 2 aged 10–14, and 7 were adults. 44 of the cases showed paralysis; and there were 2 deaths, a child of 3 who died of ascending respiratory paralysis, and an adult of 30 who died of bulbar paralysis. Paralysis involved only the limbs in 23 cases, the cranial nerves in 11, the limbs and cranial nerves in 3, and the limbs and respiratory muscles in 7.
>
> "There has been a certain amount of associated illness in contacts, which may have been abortive attacks of the disease presenting neither symptoms of meningeal irritation nor paralysis."

In the *United States* there were 421 reported cases of poliomyelitis in the week ended June 21, compared with 211 in the corresponding week of 1951.

The First Quarter in Eire

In Eire during the first quarter of this year,[1] the birth-rate was 21·8 per 1000 population, which was 0·9 above the rate for the first quarter of 1951. The equivalent annual rate for the number of deaths in the quarter was 14·4 per 1000 population, being 7·7 below that for the first quarter of the preceding year. The death-rate from all forms of tuberculosis was 0·6 per 1000 population (respiratory 0·5, other forms 0·1), compared with 0·8 (0·7 and 0·1) in the same quarter of 1951. The maternal-mortality rate was 1·2 per 1000 births registered, compared with 0·9 in the corresponding quarter of 1951. The infant mortality was 55 per 1000 births registered, compared with 58 in the corresponding quarter of 1951.

Population Estimates

The Registrar-General's estimates of the populations of local areas in England and Wales at June 30, 1951,[1] include figures for standard regions, conurbations, &c., as well as for administrative areas; and in each case the number of children under 15 is shown. These numbered at mid-1951 some 9,738,000 in a total population of 43,800,000: they represent 22·2% of the population, compared with 32·4% fifty years earlier.

Medicine and the Law

Oxygen Fatality

At a recent inquest at Hastings, reported in the *Sussex Daily News* and the *Hastings Observer* (July 5), the coroner's jury, after returning a verdict of death by misadventure, criticised the absence of definite instructions from the anæsthetist to a nursing sister with regard to the administration of oxygen.

An operation had been successfully performed upon an elderly woman for strangulated hernia. Some ten minutes later the surgeon was called to the ward. He found the patient suffering from surgical emphysema, extending from the chest to the eyes. The patient died soon afterwards. Having tested an oxygen tube near the bed, the surgeon found that it had a higher pressure than would normally be applied to a patient. The anæsthetist told the coroner that there had been no difficulty in giving the anæsthetic, apart from regurgitant vomiting. An intratracheal tube was inserted in order that material from the stomach should not enter the lungs. Directions were given that the patient should be taken back to the ward; the sister was told that oxygen would probably then be needed. No instructions were given as to how the oxygen was to be administered. The anæsthetist assumed that the ward-sister would have the necessary knowledge of the routine. The sister concerned assumed that the oxygen was to be given through the intratracheal tube; she fitted the oxygen tube on to the intratracheal tube. She had administered oxygen thousands of times before, she said, but never when a patient had an intratracheal tube in place. In answer to a juryman she replied that she did not know that the intratracheal tube fitted so tightly that the patient would not be able to breathe out. The pathologist's evidence attributed death to excessive pressure of oxygen on the lungs.

The hospital matron, called at the request of the jury, said that B.L.B. masks were kept in a store at the hospital. It might have taken five minutes to get one. She agreed that the masks might be more readily available, but they had never been needed before. The jury added to their verdict a rider that a definite instruction should have been given by the anæsthetist as to what method of administering the oxygen should have been employed.

Fatal Error in Hospital

The evidence at a recent inquest in Westminster, reported in the *Evening Standard* (July 15), explained the fatal consequence of an error in the dilution of an anæsthetic. A 4-year-old boy was admitted to hospital for the removal of tonsils and adenoids. Five anæsthetics had been administered already without trouble; the one for the boy required a greater dilution. The anæsthetist told the coroner what then happened. A small gallipot of spirit was nearly empty; he tipped the rest down the sink and washed the pot out with tap-water. He then poured in thiopentone solution and added about 20 ml. from the bowl which he presumed contained sterile water. He was deputising for the regular anæsthetist and had never been to this particular hospital before. He was used to working with a trolley containing a gallipot of coloured spirit. Thinking it was water, he mixed the anæsthetic with alcohol. Blood-transfusion, oxygen, and artificial respiration were tried but the patient died next morning from alcohol poisoning.

Asked by the coroner if he satisfied himself, by smelling it or dipping his finger in it, that the gallipot contained water, the anæsthetist replied that his mask would have prevented him from smelling it; he thought he had inadvertently dipped in a finger earlier, but he had noticed nothing. The coroner, commending the frankness of the witness, recorded a verdict of death by misadventure, adding that the hospital management committee would no doubt look carefully into the arrangements as regards the colouring of bowls containing spirits.

Self-service Sales of Drugs

In Pharmaceutical Society of G.B. *v.* Boots Cash Chemists (Southern) Ltd. (*Times*, July 17) the legality of "Boots Self Service" was examined in relation to section 18 of the Pharmacy and Poisons Act, 1933. At the company's Edgware premises the customer passed a barrier where he obtained a wire basket. On the shelves drugs, including proprietary medicines, were displayed with retail prices clearly marked. Having selected his purchase and placed it in the basket, the customer would leave the premises by an exit where a cashier would scrutinise the purchase, assess the price, and take the money. The Act prohibits the sale of a part-I poison unless "the sale is effected by, or under the supervision of, a registered pharmacist." The chemist's department at the premises in question was under the control of a registered pharmacist stationed near the poisons section. In all cases of the sale of a drug the pharmacist would scrutinise that part of the transaction which took place at the cash desk; if he thought fit, he was authorised to prevent a customer from removing the drug from the shop. Did these arrangements comply with the statute or was an offence committed?

The Lord Chief Justice said the question was whether the sale was completed before the money was paid and before the customer passed the pharmacist, or whether it was completed at that later moment. It was well-established law that a shopkeeper's exposure of goods for sale did not amount to an offer to sell. The self-service system meant merely that a customer picked up an article and brought it to the shopkeeper with an offer to buy. The shopkeeper could decide whether or no he would then sell. The very fact that a supervising pharmacist stood near the place where the money was paid was some intimation that the shopkeeper was not necessarily willing to make a contract with anyone who might pick up an article. Lord Goddard accordingly gave judgment for the defendant company.

In England Now

A Running Commentary by Peripatetic Correspondents

A PHYSIOLOGIST of our acquaintance went through a frightening experience the other night. Returning tired but happy from his daily battle with recalcitrant electrons, he found his wife lying flat on her back in the middle of the living-room floor with one hand on the upper reaches of her sternum and the other on the region of her pylorus. She was hyperventilating strongly, and there was an admiring audience of children on the sofa. The weather was fine and cloudless, the barometer was high, and the hour was 6.15.

Though a physiologist, our acquaintance has not forgotten how to take a case-history, and he shortly elicited the fact that his wife was Breathing, having found out at 5.59 from her guiding women's magazine that Breathing was Life and that Tenseness was caused by Shallow Ventilation. It also transpired that his wife had been Breathing Wrongly and Inefficiently all her life, and that he, a specialist in human function, had never observed this elementary fact; the least he could have done was to have taken the trouble to ascertain whether or not his dependants were Breathing Properly. It was no thanks to him that his children were not yet Tense and that his wife had not contracted Tuberculosis.

Our acquaintance could make but little of the situation, and was therefore glad when, after a few more minutes during which the curtains billowed and swayed in the violent air currents and the shade of the hanging light vibrated dangerously, a knock was heard on the door. Conscious of her social obligations, his wife immediately scrambled up, and, having by this time a serious alkalæmia, fell flat on her nose, scattering the audience on the sofa and disrupting a large pink balloon, the property of the smallest spectator.

Our acquaintance had his supper without further comment.

* * *

Long train journeys are tedious. Small boys can be tedious. Our train journey with our small boy threatened to be most tedious. He was filling in his latency period with what Freud laughingly refers to as *Zugnummerkrankheit*: he had noted the number of our engine before we had started, but once we were in motion he found further material too swift in transit to be recorded without cheating, and a steady flow of questions began.

Why is the smoke from the engine white when the coal is black? Who puts the pictures in the railway carriages? Is the engine-driver sitting down or standing up? My stumbling answers earned his vociferous scepticism and our fellow passengers' silent contempt. I counter-attacked by asking how many people he supposed were on the train. There was a minute of silence, more tense than restful, before he gave his considered opinion that he did not know. Did I know? We were back where we began. We contemplated our ignorance together for a while; then he suggested, "Shall I go and count them?" My wife hastily nodded and he left us to the disapproving stares of the rest of the carriage. Their thoughts were obvious: what callous parents—poor little mite—fall off the train, sure as fate. Feebly my wife and I telepathised back: no he won't—fell out of a train (stationary) last year—learned his lesson.

Presently he returned, triumphant. "145" he announced. "Fine!" we said. He glanced thoughtfully round the compartment. "Do we count these as well?" he asked. "These" registered outraged dignity and I hurriedly said that we mustn't hurt anybody's feelings. "148 and us as well!" he concluded. "What shall we do now?" "Count the ladies," I suggested. Having established that his mother was eligible, he left us once more in peace. "52" he announced on his return. "What's next?" Hopefully I recommended that he count the men and cheerfully he set off once more. But as my wife and I began to point out to each other the gap in his logic, he reappeared in the doorway and glared at us accusingly. "If you take the ladies away from everybody" he said, "the men are left behind." Feeling guilty, we tried to look surprised. I made a fighting recovery, offering him pen and paper with which to work things out. He wouldn't hear of it. "You do it in your head," he said, "It's quicker." Such faith was unnerving and I pretended to have forgotten the original figures. Our fellow passengers, on the point of reminding me and probably, in all their smugness, providing the answer as well, recoiled before my greater wisdom when I suggested that he had better go and count them all again. He considered this briefly. "It's a silly game," he decided. "You didn't tell me why the smoke was white."

Long train journeys are tedious. Small boys . . .

* * *

It is a new and exhilarating experience to sit in on a session of a Conference of Heads of Medical Departments from twenty-five territories, under the Chief Medical Officer of the Colonial Service, and to hear first-hand opinions from the ends of the earth. Development and Welfare: the Motherland must look to her laurels. How well it is understood at the limits of Empire that health campaigns in isolation have little value; they must be integrated with all the related activities—with population problems, with water-supplies, with engineering, with agriculture and indigenous food-supplies, and above all, with education.

It was exciting to hear an experience related by East Africa echoed by one from, say, the Windward Islands; a difficulty described in Malaya which proved no problem for British Guiana; or unanimous opinions from Southern Rhodesia and Trinidad.

There was a general feeling that the erection of fine hospital buildings could be disproportionately overdone—that preventive measures are the essential in the centres of population and education in the rural areas. What use to erect a hundred thousand privies if you haven't taught the people how and why they should be used? How do you set about education? Why, through the Midwifery and Child Welfare Clinics that flourish almost as familiarly as in the L.C.C. area.

But you must be careful! The comic spirit is abroad. When a highly coloured poster, designed to encourage dental hygiene in one Territory, displays an open mouth with a superabundance of dazzling teeth and a toothbrush dangling before it, beware how you transfer it! In another Territory, the local interpretation is that it must be an advertisement for a new kind of bait wherewith to catch the sharks that infest their coastal waters!

* * *

I wonder how many of my peripatetic colleagues, especially those whole-time professors who now tour the few remaining Colonies inspecting prospective medical schools, realise that if they fly more than 15,000 miles in the course of one year they are automatically depriving their dependants of all benefits under their F.S.S.U. scheme should they be involved in a fatal accident? Apparently all the leading life-assurance societies have a clause in their policies which imposes this limit on flying unless an extra premium is paid. Presumably there is a sound actuarial basis for such a restriction, but it seems rather hard lines on Sir Miles Thomas, in his valiant efforts to make B.O.A.C. a paying proposition, that the life-assurance companies consider a return flight to Singapore to carry a greater risk to life than an unlimited number of miles covered by road, rail, or sea. Personally, I would much rather fly a thousand miles with B.O.A.C. (or B.E.A.) than travel one mile in a Chicago taxi.

* * *

Comment on the N.H.S. has frequently been both pithy and pungent, but the following quotation from a North of England newspaper is surely the briefest and fiercest so far:

> "The conference will discuss malaria, tuberculosis, leprosy, cancer and the National Health Service."

No doubt in an attempt to identify the causative parasite.

* * *

". . . but surely, Brain is even more abStrauss?"

Letters to the Editor

BUTAZOLIDINE

SIR,—Now that this substance is generally available we feel it only right to point out that clinical trials in this country have been only on a small scale; and though we have ourselves seen no complications apart from reactions to injection, in the United States peripheral œdema, purpura, skin rashes, and gastro-intestinal upsets have been reported, almost always with the oral preparation and usually after several weeks or months of continuous therapy. These reactions have never to date been serious and have rapidly disappeared on stopping therapy. Kuzell et al.[1] have recently reported four cases where there was activation of pre-existing peptic ulcers; they advise the concurrent use of alkalis and suggest that more than usual caution should be observed in cardiac cases because of the risk of promoting sodium retention and œdema. Although the drug is a member of the pyrazole series no cases of leucopenia have yet been reported.

Until more is known of the drug's uses and toxic effects three general rules should be observed:

1. Careful watch should be kept on blood-counts, including platelet estimations.
2. Especial care is indicated in patients with dyspepsia, alkalis being given concurrently.
3. Sodium restriction is advisable in cardiac patients.

It would be a pity if what promises to be a useful drug should earn a bad reputation early through misuse.

Westminster Hospital,
London, S.W.1.

A. M. JOHNSON.

THE ADRENOGENITAL SYNDROME

SIR,—In your leading article of June 28 you comment on the use of cortisone in the treatment of the adrenogenital syndrome by Wilkins et al., and by Dr. Bishop and his colleagues whose report is printed in the same issue.

It may be of interest to call attention to other studies on the same subject. Thorn[2] has studied the effect of cortisone in one case of virilism. Bartter and his co-workers[3] described the same effect in three cases: Bastenie, Verbiest, et al.[4] in September, 1951, reported on the effect of cortisone in two cases of adrenogenital syndrome; and Laroche et al.[5] studied one case.

The study of Bastenie and his co-workers included chromatographic analysis of the urinary 17-ketosteroid output by Dingemanse's method. Our work has now been extended to four cases (one 14-year-old patient with pseudohermaphroditism, two adults with hirsutism and other masculine features, and one adult with simple hirsutism). In three of the four cases cortisone treatment induced temporary regression of the signs of masculinisation. In each case the various adrenal fractions of the 17-ketosteroid partition chromatogram showed a pronounced drop, affecting principally the 11-hydroxy-17-ketosteroids, which comprise fractions VI and VII in Dingemanse's fractionation and are regarded as katabolites of the glucocorticoids. The excretion of dehydroisoandrosterone (fraction III), generally accepted as a derivative of adrenal androgenic compound, was also depressed but to a smaller extent.

The depressive action of cortisone in cortical adrenal hyperfunction seems to deserve further investigation.

DEGENERATION OF THE SPINAL CORD ASSOCIATED WITH CERVICAL SPONDYLOSIS

SIR,—The paper by Dr. Bedford and his colleagues in your issue of July 12 throws new light on the mechanism of the neurological lesions in cervical spondylosis, and the description of a similar case may be of interest.

A single woman, aged 47, who had been suffering from rheumatoid arthritis since the age of 25, had become completely crippled despite several courses of treatment at various hospitals. She had had primary atypical pneumonia in 1949 and infective hepatitis in 1950; she had also suffered from recurrent conjunctivitis and iritis over the past few years.

On admission she was unable to do anything for herself; almost every joint in her body, including the intervertebral joints, was affected and the pain was barely kept under control by 8–10 tab. codein co. *B.P.* daily and amidone at night.

About six weeks after admission she noticed numbness of her left leg, and complete loss of sensation to pain and temperature was found on the left side of her body below the 7th cervical dermatome. There was no evidence of a pyramidal lesion or of muscle wasting. Lumbar puncture revealed clear cerebrospinal fluid not under increased pressure and normal in all respects. Radiography of the cervical spine at this time showed gross changes of cervical spondylosis with almost complete ossification of the disc between the 4th and 5th cervical vertebræ.

Her condition did not change significantly during the remainder of her stay in hospital, except for the development of a pressure-sore on the left buttock which responded slowly to treatment. She was finally transferred to a home for chronic invalids.

The unusual feature of this case is that the lesion seemed to be confined to the right lateral spinothalamic tract. This distribution corresponds neither to that of a vascular lesion nor to that described by Brain et al.[1] as due to disc protrusion. In the case described by Dr. Bedford and his colleagues, one of the lesions was demyelination spreading into the lateral column of the cord from a thickened denticulate ligament. The position of the lateral spinothalamic tract on the lateral aspect of the cord renders it liable to damage by traction from a thickened denticulate ligament, and this may have occurred in this case.

I would like to thank Dr. F. Dudley Hart for permission to report this case.

St. Stephen's Hospital,
London, S.W.10.

PETER R. FLEMING.

BENEMID IN THE TREATMENT OF STREPTOCOCCAL ENDOCARDITIS

SIR,—The report by Dr. Baker and Dr. Pilkington in your issue of July 5 on the use of 'Benemid' (*p*-[di-*n*-propylsulphamyl] benzoic acid) in the treatment of streptococcal endocarditis prompts us to write briefly of a similar case, in fact the one to which Dr. Douthwaite has already referred (July 12).

A machine operator, 35 years of age, had had rheumatic fever at the age of 4. His schooling was subsequently interrupted. Nevertheless, in 1939 he enlisted in the Royal Artillery and saw 6 years' active service.

In August, 1950, he first developed subacute bacterial endocarditis, *Streptococcus viridans* being found in blood-cultures on three occasions. He was treated with 70 mega-units of penicillin over a period of 72 days and responded satisfactorily. For 16 months, despite evidence of mitral valvular disease, he remained quite fit and continued normally with his work.

On March 7, 1952, he had a sudden rigor. Thereafter he felt generally unwell, sweated profusely, and complained of backache and aching in all his muscles. On admission to Guy's Hospital next day he was pale and sweating; the temperature was 99·6°F, the pulse-rate 104 per min., and the respirations 22 per min. The only other abnormalities on examination were petechial hæmorrhages in the buccal mucosa and a short pre-systolic and loud blowing systolic murmur at the apex of the heart.

---

[1] Brain, W. R., Northfield, N., Wilkinson, M. *Brain*, 1952, 75, 187.

Investigation showed a white-blood-cell count of 8000 per c.mm., an erythrocyte-sedimentation rate of 6 mm. in the first hour (Westergren), and normal urine. Repeated blood-cultures were negative. Nevertheless, the clinical diagnosis was subacute bacterial endocarditis.

With treatment by saline penicillin, even in doses of 750,000 units intramuscularly every 4 hours, the intermittent pyrexia up to 99·6°F remained unaltered. Chloramphenicol 1 g. 6-hourly and aureomycin 1 g. 6-hourly were thereafter administered as well, but the patient's condition showed no change; these two drugs were accordingly withdrawn. With the penicillin still given in a dosage of 750,000 units 4-hourly the blood-levels were estimated, with the following results:

Relation to administration of penicillin 750,000 units	*Blood-penicillin level (units per ml.)*
Immediately before .. .. .. less than	1/32
1 hour after	8
2 hours after	8
3 hours after	2

Benemid was thereupon given as well, in doses of 0·5 g. 6-hourly by mouth. Repeated estimations then showed:

Relation to administration of penicillin 750,000 units	*Blood-penicillin level (units per ml.)*
Immediately before	1
1 hour after	19
2 hours after	4–8
3 hours after	2

Notably then the patient's temperature fell to normal within 24 hours, and he remained apyrexial thereafter. His general condition improved, and the therapy was maintained thus for 43 days. During this time he received dental treatment, including the extraction of two carious teeth, all without complication. At no time was there any evidence of renal damage as evidenced by examination of the urine or estimation of the blood-urea.

When discharged on May 20, the patient seemed quite fit. His unchanged cardiac signs occasioned him no disability; he has returned to work, and now after nine weeks he seems as well as ever.

We thank Dr. A. H. Douthwaite, under whose care the patient was admitted, for permission to publish these further details, and Messrs. Sharpe & Dohme Inc., for a supply of the drug.

STABILITY OF NORADRENALINE

Sir,—We have found that the optimum conditions for stability and storage of solutions of noradrenaline (1 in 1000 of base) when enclosed in well-filled ampoules are: (1) an initial pH of about 3·6, and (2) the presence of a stabiliser such as sodium metabisulphite. When such solutions are autoclaved, the loss of activity is negligible. A solution of noradrenaline bitartrate with metabisulphite ('Levophed,' Bayer Products Ltd.) satisfies these conditions.

Solutions of noradrenaline are now being extensively used for the treatment of acute hypotension,[1] and it is important therefore to know if dilutions (1–10 µg. per ml.) are stable when stored under conditions simulating those in the operating-theatre. Dilutions of levophed were therefore made in normal saline with and without ascorbic acid (10 µg. per ml.), in 5% dextrose solution in distilled water, in plasma, and in whole blood. These dilutions were maintained at room-temperature for periods up to 12 hours and then assayed on the blood-pressure of a spinal cat, using a fresh dilution as the standard solution. Other dilutions were taken to pH 7·9 before storage for 6 hours.

RELATIVE ACTIVITY OF DILUTIONS OF NORADRENALINE
(Fresh dilution = 100%)

Diluent	Hours of storage			
	6	9	12	6 (at pH 7·9)
Saline	83	78	76	80
Saline + vitamin C ..	98	95	90	95
Dextrose solution ..	98	98	90	90
Plasma	98	95	90	90
Blood	88	80	80	80

The results shown in the accompanying table suggest that dilutions should be made in dextrose solution, plasma, or saline containing ascorbic acid; for significant losses were recorded when whole blood and saline were used as diluents. Further work showed that dilutions in an isotonic mixture of 4% dextrose and 0·18% sodium chloride in distilled water were as stable as those in 5% dextrose in distilled water.

CONTROLLED HYPOTENSION

Sir,—Venostasis by means of tourniquets to the four limbs of an anæsthetised patient may be a useful method of producing hypotension. I tried this method some years ago in a conscious subject and was not successful, but recently in an anæsthetised patient (healthy male, aged 33) the pressure dropped from 130 mm. Hg systolic to 70 mm., and rose again rapidly when the tourniquets were released.

Birkenshaw,
near Bradford.

C. G. Blakeley.

SORE THROAT AND RHEUMATIC FEVER

Sir,—May I, once again, plunge *in medias res* on the subject of tonsillectomy? I do so lest last week's letter of Dr. Alice Stewart and Mr. David Hewitt may cause the demon pantonsillectomy again to raise its head. I did not have much experience of acute rheumatism, but that may have enabled one, who gave almost daily thought for nearly forty years to the reasons for refraining from tonsillectomy, to see the problem more clearly.

Near the end of my career, I became attached to a large hospital with a big rheumatic clinic, and on the first day I was asked to go and see a case. The child had a severe attack of very acute rheumatism and there was no question of doing anything to the throat at the time. I began therefore to discuss the problem that was before us as to tonsillectomy and acute rheumatism. But the physician in charge wanted none of that; he wanted the tonsils out, and all he was asking me was "When?" I replied that it was clear that it could not be done for a long time, and when that time was approaching I would discuss with him whether it should be done. I was never asked to see that case again or any other case of rheumatism in that hospital. A "general" surgeon came in and removed the tonsils at the request of the physician when he thought it was time. But though I was debarred from discussing clinical medicine in the wards in *individual* cases, I was able to talk amicably with the physician at the luncheon table, and when I knew him well enough I got him to admit that if his views were carried to their logical conclusion it would be well for the whole population to be tonsillectomised by the age of one. In that way only could acute rheumatism be stamped out, and this disease was *the* foremost problem in national health.

Leaving alone the question of the minimum numbers that should be worked out in percentages before any conclusion is drawn from them, with tonsillectomy it is necessary to know not only that the tonsils have been removed, but into whose hands the patient had got before the operation was done. Was it the rheumatico-pantonsillectomist, or just the enthusiast for the focus-of-sepsis hypothesis? Was it at a station in which the majority or nearly 50% were set aside for operation, or in a clinic in which every aspect of the child's health was carefully inquired into, and a minimum of at least a quarter of an hour was given to the patient before the parent was advised to decide that the operation should be done. The value that can be attached to any statistics

---

1. See Swan, H. J. C. *Brit. med. J.* 1952, i, 1003.

very largely depends upon which of these sources they came from.

But there is another thing. Clincial medicine is an art, and must ever remain so; but science must be applied to it, and one way of applying it is by checking the art by the laboratory whenever it is possible to do so. And with tonsillectomy this is possible by sending every tonsil that is removed to the laboratory for investigation bacteriologically. The decision to remove tonsils is an assessment of a bacteriological probability; and I do not think that any statistics today should be put forward unless they include the organisms found in the tonsils after removal.

The first paper I ever wrote was read at the Medical Society in March, 1914, and was entitled Tonsils and Adenoids in Children: a Plan for Fewer Operations. Since then the tonsillectomy-rate, with a few local remissions, has steadily gone up until it reached, in at least one area, 50% of the population by the age of 5. In the last five years, I am told, it has been receding. It would be a pity if a letter from a scientific institute, which carries with the profession and with parents so much more weight than the experience of clinicians, should result in this operation-rate starting to climb again; especially now that it seems that acute rheumatism may be stamped out without operation.

Lingfield, Surrey. T. B. LAYTON.

CALCIFEROL IN PULMONARY TUBERCULOSIS

SIR,—Dr. Jackson (June 7) states: "a controlled trial of calciferol given with streptomycin and P.A.S. has been made." It appears that his cases were treated for six weeks, and then assessed radiologically. The only permissible conclusion (and one may question the value of conclusions drawn at the end of six weeks' therapy in pulmonary tuberculosis) should therefore be that six weeks' combined treatment of unselected cases gave results no different from six weeks' chemotherapy alone. I am not surprised. The cases which we described[1] had been treated for 4–6 months and observed for 12–18 months. It is true that Dr. Jackson says that in a few of the 'Sterogyl' group, chemotherapy was continued for a further 6 weeks, but this presumably applies to the streptomycin-P.A.S., and not to the calciferol. Having taken the trouble to investigate the treatment, it seems a pity that he did not continue for a longer period, which a consideration of the results in lupus vulgaris would indicate to be necessary. He found no contra-indication to the use of calciferol in this way; why then were conclusions drawn after so short a time?

It is worth while emphasising that calciferol is one of the few chemically defined substances known to have an effect on the host reactions in tuberculous lesions. It is difficult to obtain direct evidence of tissue reaction in pulmonary disease. However, in some later cases treated at Paddington Hospital in which 600,000 units sterogyl was injected twice weekly for a month, followed by one injection a week for a further month, an interesting change in the character of the sputum was observed. After the second or third injection, the sputum became uniformly rusty pink. This persisted for 2 or 3 days, then disappeared, to reappear following the next injection. This succession of events was seen for 2 or 3 weeks. It is strikingly similar to the stage of congestion observed in lupus during the early stages of calciferol treatment, and is additional evidence that the reaction in pulmonary disease is of the same kind as that seen in cutaneous tuberculosis. This is the essential point of the case I have presented. The manner in which this phenomenon may be best utilised in therapy still requires investigation.

New-Delhi, India. J. FIELDING.

SUCCINYLCHOLINE

SIR,—We wish to thank Dr. Bourne and his colleagues for their excellent contribution, published in your issue of June 21. Dr. Franks (June 28) says that "there appears to be no indication beforehand of the amount of muscular activity to be expected with the initial dose of the drug." Some of his muscular patients showed only minor muscle-fibrillation, whereas other similar patients had rather severe convulsions. Our experimental and clinical observations over the past two years may be of interest here.

Experiments in animals (cats and rabbits) and in volunteer medical students have shown uniformly that the degree of muscle-fibrillation (twitch) depends primarily on the rate of the injection. In man injection of 20–30 mg. succinylcholine in less than 10 sec. invariably gave rise to a "twitch-reaction" of varying degree. In most cases the same dose administered in the course of 10–30 sec. resulted in less muscle-fibrillation, and in about 25% of the cases no "twitch" was seen. When the same dose was infused (mechanically) in the course of 30–60 sec., almost no muscle-fibrillation resulted.

The "twitch-reaction" was recorded by means of needle electrodes in muscles of the limbs. The potentials were studied on an oscillograph. Muscular and respiratory paralyses were observed in these experiments and measured by means of ergographs and spirometer (Krogh). The muscular contractions were produced by electric stimulation of different motor nerves. In most cases the paralysis following rapid injection was complete and of short duration (1–2 min.). After slow infusion the paralysis was less pronounced, but of longer duration (2–3 min.).

Two years' clinical experience, including patients undergoing general surgery and electric convulsive therapy (about 2000 administrations), has confirmed these experimental results.

Municipal Hospital, Copenhagen. HENNING POULSEN.
G.E.A. Ltd., Copenhagen. WILLY HOUGS.

SIR,—Dr. M. L. Mackay describes in his letter of July 19 respiratory arrest in a woman weighing 12 stone, which lasted six and a half hours after injection of 50 mg. of succinylcholine. He finds this difficult to explain on the basis suggested by Evans et al.[1]—i.e., that succinylcholine sensitivity is caused by a low serum-cholinesterase level.

It may be pointed out that Bourne et al.[2] found a significant difference in the serum-cholinesterase level when they compared 6 patients recovering normally from succinylcholine and 6 whose response lasted beyond eight minutes. Day[3] found that a patient weighing 10 stones responded to a dose of 50 mg. with seven and a half minutes apnœa; 20 mg. produced a reaction lasting three minutes; and after six subsequent injections of 40 mg., there was a reaction lasting 6 minutes.

Dr. Mackay himself suggests that the injection of neostigmine must have played a part in the prolonged apnœa seen in his case, and, in fact, considering his experience from the enzyme-chemistry point of view, one must conclude that injection of neostigmine after 35 minutes must have been the cause of the very prolonged apnœa. If the short action of succinylcholine depends on its rapid destruction by serum-cholinesterase, the injection of a powerful inhibitor of this enzyme—in what was presumably a patient with a very low serum-cholinesterase level to begin with—would delay recovery almost indefinitely.

There may well be other mechanisms of succinylcholine removal: in the absence of the enzymic defence mecha-

nism, excretion by the kidneys may play a part; but there seems to be no reason at present to consider anything other than serum-cholinesterase activity.

To produce dramatic delay in recovery, the enzyme level must obviously be very low, and Callaway et al.[4] have shown that there is little chance of encountering such cases in an average sample of the population. Bourne et al. found only 5 among 546 patients in whom the reaction lasted longer than eight minutes, and Evans et al. encountered the first case of prolonged response only after they had employed succinylcholine more than 400 times. If patients likely to have a low serum-cholinesterase level (those with liver-disease, anæmia, malnutrition, and possible polyphosphate poisoning) are excluded from succinylcholine treatment, and if it is realised that neostigmine is contra-indicated after this drug has been given, the use of succinylcholine should be quite safe. It is obvious that no drug producing apnœa should ever be given unless facilities for artificial respiration are available.

Once it is quite clear in the minds of anæsthetists that prolonged response to succinylcholine is due to delay in destruction of the drug by serum cholinesterase, *they will stop giving a cholinesterase-inhibitor*, such as neostigmine. The obvious treatment, if any, will be to increase rather than lower the enzyme activity; transfusion of fresh blood or plasma should serve this purpose, and it is noteworthy that even blood stored for several weeks has in its citrated and diluted plasma esterase levels varying from 30 to 50 units.

H. LEHMANN.

SIR,—Following recent articles on the use of ultra-short-acting relaxants, an account of a small series in which repeated doses of succinylcholine chloride ('Scoline') were given may be of interest.

On theoretical grounds it seemed that appendicectomy would be the operation of choice for the exhibition of this agent. It should be possible to maintain light anæsthesia throughout, while providing relaxation when required—that is, until the delivery of the appendix, returning the gut to the abdomen, and closing the peritoneum. Should difficulties be encountered, the relaxation could be prolonged indefinitely by giving repeated doses.

Of 30 cases of appendicectomy in the series, 25 were emergencies. The 11 "difficult" cases included 3 in which paramedian incisions were made; the longest operation lasted fifty minutes, and the shortest ten; the age-limits were 12–58.

Premedication was usually morphine gr. $^{1}/_{6}$ and atropine gr. $^{1}/_{100}$. The *induction* was by *thiopentone*, usually 0·5 g. Maintenance was by nitrous oxide and oxygen from a Boyle's machine delivered via a Coxeter Mushin apparatus. 'Vinesthene' was placed in the chloroform bottle, and the lever left just above the minimum position. A flow of 5 litres per minute of nitrous oxide and 1 litre of oxygen was attempted,[5] but usually it was necessary to reduce the proportion of nitrous oxide to avoid hypoxia. Succinylcholine was given in 5% solution from a 10 ml. syringe strapped to the arm. Assisted or controlled respiration was given when necessary.

5 further patients (i.e., 5 out of 35) were adequately relaxed *without succinylcholine*. Of 4 *cases in which* vinesthene was not given, only 1 was satisfactory.

Recovery was rapid, usually within fifteen minutes. One patient's recovery was delayed an hour. This patient was a fat chronic bronchitic who had an exacerbation lasting four days. One other chronic bronchitic had a temperature of 99·2 F for one day. There was no other postoperative morbidity, apart from that due to preoperative infection of the pelvis.

The technique has so far fully confirmed the theoretical expectations.

The initial dose is 10 mg., and from the response to this the size of subsequent doses is judged. In the "difficult" cases, where prolonged relaxation is required, the optimum relaxing dose and its duration is determined, usually by the second or third dose; and this is then repeated as long as relaxation is required. Each dose is given thirty seconds before the previous dose will wear off. This timing is most important, as the sudden return of abdominal tone may cause the rupture of a friable viscus. The "simple" case usually requires one or two doses before the appendix is delivered, and one for closing. Sometimes it requires one dose only or none.

The usual relaxing dose is 5–15 mg., which causes apnœa or inadequate, shallow respiration. Commonly adequate spontaneous respiration returns before abdominal tone; sometimes respiration remains adequate throughout. Relaxation starts twenty to thirty seconds after injection, and lasts two to four minutes. During a given operation the same dose always has the same effect, plus or minus a few seconds, thus permitting the accurate timing of repeated doses. No additive effects, and no case of prolonged action, have yet occurred.

The doses of succinylcholine suggested are smaller than those previously recommended. This is probably because an attempt has been made in each case to give a dose which provides relaxation without rendering respiration inadequate, while the nitrous oxide and vinesthene anæsthesia will also reduce the dose required. Whether it is possible to retain spontaneous respiration still seems uncertain. Swedish workers, using a drip, claim that this is possible, while British workers doubt it.[6] My own small experience indicates that with the technique described it is possible at least in some cases. It would seem probable that the level of the accompanying anæsthesia, and the degree of respiratory depression that it causes, is the deciding factor.

Whatever the place of succinylcholine in more extensive operations, I suggest that for appendicectomy it is a very useful agent. The advantages are: a light level of anæsthesia accompanied by profound relaxation when required; absence of toxic effects; complete control; and rapid recovery.

AS A PATIENT SEES IT

SIR,—Your annotation of July 12 tempts me to write of my all too present experience as a patient.

The untiring kindness of the nurses is beyond praise; but surely the most terrible thing to bear is the deadly monotony of hospital routine. On many occasions I have tried to break through this, but with no success. I give two examples.

Quite early on in my stay in hospital I asked whether the Bible, prayerbook (shortened version), and hymnbook (A and M) which were beside my bed could be moved to the far side of the books (including a Bible) which I had brought in with me. A very serious-faced probationer replied: "It is a rule of the hospital that the Bible, prayerbook, and hymnbook must be next the patient."

The second attempt was no more successful. After many weeks in the hospital I said, rather tentatively, to the nurse who was making my bed: "How would you react were I to ask if, just for a change, I could have my counterpane the other way round?" "Oh," she replied without a moment's hesitation, "we should call you a Socialist."

A PATIENT.

OSTEOPATHY AND ORTHODOXY

SIR,—I have no sympathy for your peripatetic correspondent (July 5) in his chagrin at learning that an osteopath had employed a form of orthodox treatment. If he and some of his colleagues were as quick to appreciate the value of osteopathic treatment, in appropriate cases,

PLEA FOR PSYCHOTHERAPY

SIR,—In recent years there has been a spectacular advance in the physical treatment of psychiatric illness. Electric convulsive therapy alone has revolutionised the prognosis of involutional depression. In schizophrenia the chances of a remission are sufficiently good to justify treatment by insulin coma. Leucotomy has undoubtedly made bearable and even useful the lives of patients who have hitherto been a misery to themselves and a burden to their friends. Various abreactive techniques have made it possible to release deeply repressed, painful complexes and thereby, in some cases, have produced a dramatic relief of symptoms and in others have shortened analytic procedures.

On the other hand, the glowing hopes aroused by the pioneer work of Freud for the solution of all psychiatric problems by psycho-analysis have faded after many disappointments, and the pendulum has undoubtedly swung away from treatment along mental lines to treatment by physical methods.

The problem of body-mind relationship has so far been insoluble; but one can perhaps claim that there is no proof that mind has not an autonomy of its own, and that there is a case for attacking some problems along mental lines. In the past psychotherapy has had, as well as many failures, considerable successes. These must depend firstly on correct diagnosis, and secondly on a flexible attitude to the methods of attack to be used in each case. At the present time there would seem to be a danger that in the altogether laudable search for short-cut methods, preferably physical, the value of psychotherapy may be forgotten. Even where physical methods or abreactive techniques relieve symptoms in a dramatic way, relief may not be permanent without a change of mental attitude; and in other cases nothing but a patient understanding and unravelling of the patient's psychological problems can give the help which is required.

London, W.1. MARION GREAVES.

TREATMENT OF ANURIA

SIR,—In referring (July 5) to my short contribution to the discussion on the Treatment of Anuria at the Royal Society of Medicine on June 26, you unfortunately misquoted my remarks on its therapeusis.

I had attempted to show that embryologically the kidney was a "neurile" organ; that the comparative physiology of the salmon and of the eel afforded evidence that change of environment produced prolonged "anuria" from which renal recovery was complete; that controlled experiments had evoked acute tubular necrosis by nervous pathways; that there was considerable pathological evidence to show that cortical renal ischæmia and medullary congestion was the post-mortem change in such states, and that all this could be explained by the Trueta mechanism of whose occurrence under physiological and experimental pathological circumstances I brought strong proof. Especially I emphasised Bykov's conditioned-reflex experiments where antidiuresis could be provoked in animals with diabetes insipidus, indicating the paramount importance of the glomerulus in urine production.

My theme was that anuria was due to the "shunt," and was reversible even at late stages by conduction anæsthesia; also that the disturbance the "shunt" produced in the electrolyte and water environment itself offered a stimulus to renal shut-down. Modern therapeutics were content to deal with the latter alone, whereas the clinical results of Hingson's ('Pavex') caudal technique supported the theory of spasm and recovery from it even in late stages. Since then the remarkable results of Dr. Chatterjee[1] have given the strongest evidence of the correctness of my view.

London, W.1. JOHN SOPHIAN.

THE NORMAL TEMPERATURE

SIR,—What is the normal human temperature? It has been long accepted as 98·4°–98·6°F taken by clinical thermometer in the mouth. For myself, I no longer accept this as correct. I have not kept records, but I long ago came to the conclusion that for most people the normal sublingual temperature is rarely higher than 97·6°F and not infrequently is less by up to a degree and a half. There are, I think, slight environmental variations—due to atmospheric conditions, the processes of digestion, &c.—but these variations are by no means considerable.

I base my contention on observation over many years. In fact I have come to regard a temperature of over 97·6°F in an ambulant patient as a raised temperature requiring further investigation; more often than not I have been justified, although the lesion may have proved to be no worse than a mild gingivitis or a rhinitis.

London, W.C.2. G. RALSTON.

PLACENTAL CONTENT OF A.C.T.H.

SIR,—Dr. Böe and Mr. Salvesen (June 14) describe data which show that adrenocorticotrophic hormone is not contained in the human placenta. These workers have used physiological saline with 0·25% acetic acid to prepare their extracts.

In this laboratory we have attempted to confirm the work of Tarantino,[2] Jailer,[3] and Opsahl,[4] all of whom claim to have demonstrated the presence of A.C.T.H. in the placenta. We have utilised the glacial-acetic-acid extraction method of Payne et al.,[5] followed by oxycellulose adsorption.[6] 20 g. lyophilised tissue (full-term placenta) yielded 40 mg. of solids in the oxycellulose eluate. The material isolated by these procedures was assayed by the ascorbic-acid depletion method of Sayers et al. and was found to contain approximately 0·01 international units (I.U.) of corticotrophin per mg.

Thus placental tissue may be calculated to contain 4–5 I.U. of A.C.T.H. activity per kg. fresh tissue, which represents a much larger concentration of corticotrophic activity than may be ascribed to the blood present in the tissue, inasmuch as Sydnor and Sayers[7] have found the concentration of normal blood to be less than 0·01 I.U. per litre, whereas Granirer[8] has shown that postpartum plasma contains about 1 I.U. per litre.

Obituary

HUGH WILLIAM BELL CAIRNS

K.B.E., M.A., D.M. Oxfd, M.B. Adelaide, F.R.C.S., Hon. F.R.A.C.S.

ALIKE as a surgeon, a leader, and a friend, Sir Hugh Cairns will be gratefully remembered. His death at the age of 56 must sadden all who appreciated his skill, his vision, his resolution, and his devotion to medicine. But he had done much of what he set out to do; and through his mastery of neurological technique and team-work he had left a deep impression on those he taught. His methodical approach, his self-discipline, and his helpfulness will be continued through them.

The only son of a Scottish father and an Australian mother, he was born and brought up in Adelaide, South Australia, where he did well at the High School and the University. During the first world war he served in the Army, first in the ranks, and then, after qualifying at Adelaide in 1917 at the age of 21, with a commission in the Australian Army Medical Corps. Having seen active service in the Middle East and in France, he came to this country in 1919 as a Rhodes scholar at Balliol, and he rowed in the Oxford boat in 1920. He worked as a demonstrator in the anatomy department, and was house-surgeon at the Radcliffe Infirmary, before going on to the London Hospital in 1921. In the same year he took his F.R.C.S., and after holding house-appointments and working in the pathology department, he became first assistant in the surgical unit. In the next few years his interests were mainly in genito-urinary surgery, and he wrote on tumours of the testicle and on congenital cystic kidney. As an operator he was distinctly slow; and he was intelligent rather than specially clever. But he was alert, inquiring, and entirely dependable—a strong man to whom nothing was too much trouble. With characteristic insight the late George Riddoch saw that these qualities could be put to particularly good purpose in neurosurgery as practised by the school of Harvey Cushing in Boston, and he persuaded Cairns that there was an opening in London for a neurosurgeon who had learnt Cushing's methods. In 1926 the next appointment to the London Hospital staff was anticipated by electing Cairns supernumerary assistant surgeon, and he was given leave of absence to go with a Rockefeller fellowship to the United States, where he became assistant resident surgeon in Harvey Cushing's clinic in Boston.

[Stoneman

The Medical Research Council report [1] which he wrote on his return showed how strongly the elaborate American technique appealed to Cairns: the fullest possible examination, the most careful operation, and the most detailed notes, so that surgery and science might advance—this was the way, he felt, in which medicine should be practised. But he had learnt not only technique but also much else for which Cushing stood. He set himself to become, so far as he could, his own neurologist, and to combine research with practice. He adopted, too, the American plan of conducting his private practice in the building where he did his hospital work, believing (courageously but rightly) that the man tells more than the address, and that, if he made himself good enough, patients would come to Whitechapel to consult him. In fact, however, he was little interested in whether patients were private or not: what he chiefly wanted was the right conditions for his work. Neurosurgery, as he saw it, was a highly coöperative affair, and with his team of assistants and ancillaries, his dictaphones, and his operations lasting hour after hour, he represented the New Model in British surgery. The way was not always easy, and if in dealing with patients Cairns always had the gentleness of strength he could also display some of its ruthlessness when he felt that opposition must be broken down. In the ten years after his return from Boston he gradually earned himself a great reputation; and he was appointed to the two principal London neurological hospitals, at Maida Vale (1931–34) and Queen Square (1934–37). For a long time, however, he had cherished the hope of forming a rather different kind of neurosurgical institute—perhaps out in the country—where the art and the science could be developed more deliberately and without distractions. He was by nature an organiser and planner, of a highly practical kind, and he was interested in education as well as research. When, therefore, he came into contact with Lord Nuffield he was well prepared to advise that potential benefactor on what might be done at Oxford, and his appointment to the Nuffield chair of surgery in 1937 enabled him not only to play a leading part in the development of the clinical medical school but also in due course to create one of the world's foremost neurosurgical clinics.

Too soon, however, the war intervened; and Cairns became first the Ministry of Health's adviser on head injuries, and then consulting neurosurgeon to the Army, with the rank of brigadier. In this capacity one of his best-known achievements was the prevention of many head injuries by compelling Service despatch-riders to wear crash helmets; and another was the field trial he organised with Sir Howard Florey in which the use of penicillin for battle casualties was tested in various theatres of war. Even more benefit, however, came of his steady determination that the treatment of head wounds and injuries by field units should be of the highest possible standard, and he could share the credit for a death-rate for such casualties that was lower than in any other army. In Oxford he was at the same time organising the Head Injuries Hospital in St. Hugh's College, and the wartime organisation for the treatment and reablement of head injuries which he developed with Sir Charles Symonds made many important contributions to knowledge and to the efficiency of the Army and R.A.F. medical services.

After the war there were many claims that took him away from Oxford. As an organiser he was becoming more patient, and in a presidential speech to the Association of Surgeons in 1947 he remarked that "in this university institutions and departments don't mature quickly," but he hoped that the right conditions would develop in the next ten years. On the same occasion he deprecated standardisation of surgical types and spoke of the advantages of a mixture after the English manner; and he also believed strongly in the value of bringing non-medical scientists into medical research teams. In the following year he was visiting Australia and New Zealand as first of the Sims travelling professors; and his later tours in the southern parts of Africa made him plead earnestly that the profession at home should take more interest in the medical needs of the African continent, where action, he thought, could bring such great results. But with these and other obligations, he remained the vigorous head of a department that has been producing valuable work on tuberculous meningitis, on antibiotics in intracranial surgery, and latterly on alternatives to leucotomy.

"He was amazingly easy to work with," writes W. R. R., "for he never bothered with petty matters of prestige, or who should be in charge of this or that. He was always appreciative of the work of his colleagues, and provided every facility to further their researches. He formed the most important training-ground for neurosurgeons in this country, and there must be over a score of his trainees who have themselves formed similar neurosurgical clinics in many parts of the world. He played the game of life with an enthusiasm and an insistence on the highest possible standards which were an inspiration: his work was his life, and holidays were short intervals during which vigorous physical activity strengthened him for the next session. He was always convinced that things could be improved, and his insistent pressure for changes naturally provoked opposition at times; but his motives were so transparently honest and sincere that he usually gained much support. Those of us who were privileged to work with him were accustomed to leave to him the most important administrative aspects of our work, for we had such complete confidence in his judgment regarding such matters. We had looked forward to many more years of happy collaboration, but as this cannot now be we must maintain what he has built."

---

[1] *Spec. Rep. Ser. Med. Res. Coun., Lond.*, No. 125, 1928.

"In Cairns's success," writes W. R. B., "there were many ingredients. An athletic physique, an untiring capacity for work, manipulative skill, and high intelligence all played their part; but a man may have all of these and yet be no more than a first-rate exponent of his art. Cairns added to them an imaginative vision, which served him alike in his everyday activities and in larger affairs. He had an unusual insight into his patients' point of view, which was invaluable both in taking a history and in the management of treatment, and contributed to his minute attention to detail. His approach to larger questions was empirical, and guided by an intuition which led him successfully to explore possibilities in research and treatment. His professional life was a pilgrimage, from general surgery to neurosurgery, and from the London, Maida Vale, and National Hospitals to Oxford, because at each step he saw before him bigger opportunities to use his ability. He lived with a humorous zest, which sprang from some perennial youthfulness. One could not picture Hugh Cairns as an old man; and now he 'shall grow not old, as we that are left grow old.'"

The following is a tribute from one of his pupils.

"Cairns was above all a teacher, not in the didactic sense, but by precept and example. Just as Cushing had left his imprint on him, Cairns left his mark on all of his pupils and he derived the greatest pleasure from watching their progress. During the hectic years in London, he gave the impression of being a stern master, but beneath the surface of hard work and rigid discipline there was a warm heart and keen appreciation of effort. No-one was ever ticked off for an error of judgment or mistaken diagnosis unless it was the result of lazy thought or action. It was in the busy practice of the London Hospital that he established his reputation, and by the standards of those days, in a comparatively short time. He had the gift of investing every case with a particular interest, and his system of records made the material easily available for future reference. Each patient was 'followed up,' and over the years a useful body of information about the natural history of neurological diseases has accumulated. He had a great respect for pathology, and he often spoke of his association with the pathology department at the London as being one of the most valuable parts of his own training.

"When he left London for Oxford, a certain mellowing was soon apparent. He worked as hard—as did everyone else—but it was all done in one place and more efficiently than had been possible in London. There was time for an occasional round of golf at Huntercombe, tennis in his own garden, wooding expeditions on Sunday afternoons, and family holidays at South Stoke and Bamburgh. He enjoyed giving parties and arranging functions, and was an excellent host; one of his happiest memories was the occasion of Cushing's visit to Oxford to receive his honorary degree when they were surrounded by mutual friends from all over the world. But these activities were only adornments of his work, and his output was increasing all the time.

"The war interrupted much of this pleasant way of living. He was thrown into the development of the undergraduate clinical school in Oxford and this remained one of his chief interests. There were difficulties, and it is not surprising that the motives of one with such a dynamic personality should be occasionally misunderstood; but his interests were always the best interests of medicine in general, and the Oxford school in particular, as he saw them. His influence in the councils of his colleagues increased steadily during and after the war. At the same time the war presented the problem of head injuries, and with Sir Charles Symonds he developed an organisation which was unequalled anywhere. The same qualities which had made a success of his departments in London and Oxford found even more fruitful application in the larger field of battle casualties. Even during these strenuous years, he never lost sight of the value of records or the importance of training young surgeons, and there was about St. Hugh's much of the atmosphere of a teaching hospital.

"After the war, he had to spend more time on administration and ambassadorial duties, and there was less time for routine clinical work. This was a considerable loss, because he was essentially a good doctor and was at his best immersed in clinical problems and dealing with ill people and their relatives. But he was able to spend more time on the scientific projects in which he was interested, and his approach became much more philosophical. Although he had had no formal training in research techniques, he had learned a great deal by study and observation, and his own researches were models of thoroughness, clarity, and critical assessment. He was to the end a student, eager to learn from anyone who knew more about a subject than he did, and his interests were by no means confined to his own specialty. It was these qualities, together with his charming personality, which made him such a good representative of British medicine.

"The brisk walk, the flashing eyes, the firm lower jaw, and the quick smile are no longer with us; but none of us can ever forget the indomitable spirit which has been and will remain our inspiration."

Hugh Cairns married in 1921 Barbara, youngest daughter of A. L. Smith, then master of Balliol. They had two daughters and two sons, one of whom received the degree of D.M. at Oxford a few weeks ago.

ROBERT WILLIAM CRAIG

O.B.E., M.D. Edin., F.R.C.P.E., F.R.S.E.

Dr. R. W. Craig, who was for fifteen years Scottish Secretary of the British Medical Association, died at his home in Edinburgh on July 14.

He graduated M.B. at Edinburgh University in 1903, and held various house-appointments before he succeeded to his father's general practice at Pathhead, Midlothian. He remained in practice there until 1931 when he was appointed Scottish secretary to the B.M.A. For nine years he was a member of the Midlothian education authority and convener of its medical committee. Shortly after joining the staff of the B.M.A., he was made a member of the Cathcart Committee, which from 1934 to 1936 studied and reported on the Scottish health services. He was appointed O.B.E. in 1941 in recognition of his work in the organisation of civil defence in Scotland.

[Kemp, Dalkeith

In 1943 Dr. Craig became a member of the Scottish Old People's Welfare Committee and later he was elected chairman. For many years before his death he sat on the General Medical Council as a directly elected representative from the profession in Scotland. At the start of the National Health Service he became a member of the Scottish South-Eastern Regional Hospital Board and he served as its vice-chairman until he retired in 1951. His public appointments thus brought him into close contact with a great many people in Scotland, and the circle of his friends was enormous, for he was an open-hearted and friendly man, with the inestimable gift of always remembering faces and being able to attach the correct names to them.

A memorial service was held on July 20 in Crichton Church, in the district where Dr. Craig formerly practised.

Mr. J. O. D. WADE

T. G. I. J. writes: "All who studied anatomy and surgery at Cardiff will recall 'Jimmy' Wade's phenomenal memory for the minutest detail of anatomy and his remarkable speed and dexterity in operating. He made emergency surgery, especially the acute abdomen, his specialty—indeed, no-one in this country had wider experience in this field. He was always ready—day and night—to respond to the many calls for his skill, and his work for the people of South Wales, particularly in the mining valleys, was colossal. A kind and encouraging chief, he was a great support to his house-surgeons, to whom he was always available. After a night of operating it was a privilege and an education to walk home with him—his arm resting on one's shoulder—while he discoursed on the many facets of the surgery of a vast experience."

Appointments

BRAIN, R. H. F., M.B. Birm., F.R.C.S.: asst. surgeon and asst. thoracic surgeon, Guy's Hospital, London.
CRANE, J. E., M.B. Wales: appointed factory doctor, Carmarthen district, Carmarthen.
DEAN, THOMAS, F.R.C.S.E., M.R.C.O.G.: part-time consultant obstetrician and gynæcologist, St. Helen's Hospital, Barnsley, and Montagu Hospital, Mexborough.
FARQUHAR, J. V. L., B.A. Camb., M.R.C.S., D.P.H.: asst. county M.O. for Staffordshire and M.O.H. for Tamworth.
LUKER, B. C. H., M.B. Camb., F.R.C.S.: consultant surgeon, Montagu Hospital, Mexborough, and Moorgate Hospital, Rotherham.
MCCLEMENTS, D. T., M.B. Edin.: senior house-officer (surgical), Edenhall Hospital, [illegible] ian.
MACLEAN, A. B., M.B. [illegible] L.F.P.S.: asst. surgeon (consultant), East [illegible]
TOLLAND, JOHN, L.R.C.P.E., D.P.H.: M.O. to Newcastle-under-Lyme area health committee, asst. county M.O., and M.O.H. of Kidsgrove Urban and Newcastle-under-Lyme Rural Districts.

Leeds Regional Hospital Board:

BENIANS, R. G., M.A., M.D. Camb.: asst. chest physician (S.H.M.O.), Bradford chest clinic.
BOWEN, W. A. L., M.R.C.S., D.P.M.: consultant psychiatrist and medical superintendent, Naburn and Bootham Park Hospital.
WINN, CECILIA, M.R.C.S.: asst. anæsthetist (S.H.M.O.), Ilkley and Otley, Menston, and Middleton and Grassington groups.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

BARROWCLIFF.—On July 4, at Stratford-on-Avon, to Germaine, wife of Dr. D. F. Barrowcliff—a daughter.
GARROD.—On July 17, at the British Military Hospital, Benghazi, M.E.L.F. 6, to Gwyneth (née Glynne), wife of Captain D. C. H. Garrod, R.A.M.C.—a son.
HERBERT-BURNS.—On July 6, at 18, Edward Road, Dorchester, to Joan (née Jolly) and Dr. Jack Herbert-Burns—a daughter.
IMRIE.—On July 15, at Mount Alvernia, Guildford, to Diana, wife of Dr. David A. Imrie—a daughter.
ODELL.—On July 17, at the South London Hospital, S.W.4, to Ruth (née Licence), wife of Dr. J. R. Odell—a daughter.
PEATFIELD.—On July 13, to Ruth (née Wilson Hall), wife of Mr. Ronald Peatfield, F.R.C.S., the Fairway, Green Lane, Oxhey—a son.
ROWLANDSON.—On July 17, to Rosamund (née Firth), wife of Mr. Richard Rowlandson, F.R.C.S., the Gables, Henlow, Beds—a son.
SHEAHAN.—On July 14, at Central Middlesex Hospital, N.W.10, to Lorna (née Leader Williams), wife of Dr. Christopher Sheahan—a daughter.
YATES.—On July 11, to Alison (née Walker), wife of Dr. P. C. Yates, of 404, Stirling Highway, Cottesloe, Western Australia—a son.

MARRIAGES

DAVIES—VAN LEUVEN.—On July 19, in London, Howard Davies, M.D., to Brenda Van Leuven, M.R.C.P.
LINDAN—JACKSON.—On July 17, in London, Olgierd Lindan, MED. DIP., to Rosemary Jackson, M.B.

DEATHS

BAIRD.—On July 18, in London, Stephen Young Baird, M.B. Glasg., of Assam, India.
CAIRNS.—On July 18, at the Radcliffe Infirmary, Oxford, Hugh William Bell Cairns, K.B.E., D.M. Oxfd, M.B. Adelaide, F.R.C.S., Nuffield professor of surgery in the University of Oxford, aged 56.
MITCHELL.—On July 19, at Ben Mohr, Insch, George Mitchell, M.B. Aberd., L.M.
O'REILLY.—On July 15, Charles Joseph O'Reilly, D.S.O., M.C. and bar, Knight of St. Gregory, M.B. Dubl., lieut.-colonel R.A.M.C., Roseboro', Naas, co. Kildare.

Notes and News

IMPERIAL CANCER RESEARCH FUND

To mark the 50th anniversary of the foundation of th Fund, the president and council held an At Home at th Fund's laboratories at Mill Hill on July 15. Exhibits a demonstrations were arranged to illustrate the story of th Fund's work since 1902, and to show what is going on at th moment.

Dr. James Craigie, F.R.S., director of the Fund, and D A. M. Begg have continued their investigations using tumou preserved as cell suspensions in the frozen state. Some ce have now been kept alive in this way for $3^1/_2$ years. Mr. H. Crabtree presented some of his results with the azo-compoun that he has been synthesising and examining to explore th idea that *p*-aminobenzoic acid may play some part in th genesis of liver tumours. Mr. P. C. Williams's research mammary cancer in mice is designed to answer the questio can hormonal differences account for the different prevalen of cancer in three strains of mice? As a first step, he h studied the effect of subcutaneous injections of stilbœstr on vaginal smears of spayed mice; sensitivity is shown cornification of the epithelium. There are many variabl and the work is necessarily long; for example, some anomali that have turned up may be caused by climatic changes- a factor which can only be taken into account by analysi results for at least a year. When the experiments are extend to intact animals, the further complication of the œstro cycle will be introduced. The next step will be to deci whether mammary and vaginal sensitivity can be correlate Dr. L. M. Franks's demonstration included an account work on the spread of prostatic carcinoma to bone. T injection of a barium suspension in male cadavers has enabl a direct communication between the prostatic veins, t vertebral venous system, and the veins of the pelvic bon to be shown radiographically. Spread along these vei seems a likely cause of bony metastases. The routi investigation of human breast cancer was dealt with Dr. G. D. Lumb and Dr. J. Strotton Young. The "giant section technique, in which sections of frozen tissue are c with a band-saw, enables large areas to be examined micr scopically in one specimen, and is very useful in tracing loc spread of tumour cells.

MEDICINE IN ABORIGINAL SOCIETIES

FINAL students, oppressed by the complexity of mode medicine, may like to know that even in less hackney societies the Art is elaborate, technical, illogical, contradictor uncertain in its results, and long to learn. So much is evide from an exhibition illustrating "The Medicine of th Aboriginal Peoples in the British Commonwealth," open by Lord Webb-Johnson at the Wellcome Historical Medic Museum on July 18. Moreover, as Dr. E. Ashworth Unde wood hints in his informed introduction to the fine illustrat catalogue,[1] the aboriginal curriculum, too, has its burdens.

There are, he says (and it has a homely sound), sever grades or degrees of medicine men in the same area. Studen need a high sense of vocation, amounting in fact to a convictio that they are born for the part; for when a young ma decides to take up medicine he retires to a desert place an falls into a trance, perhaps induced by fasting, and havin thus passed his entrance examination, is admitted to th initiation rites—which, among the Aruntas of Australi include having a hole bored through the tongue, perhap to help him to think before he speaks. He then settles dow to a long period of training in a school for medicine me When he finally gets into practice his daily round does n differ as much as might be expected from that of his mo urbane counterpart, except that he is granted consulta status from the outset. Most aboriginals, in fact, on call in the doctor as a last resort, relying on simple hom remedies to deal with such trifles as colds, measles, toothach smallpox, snake-bite, bee-stings, and jiggers. The medici man is reserved for occasions when an enemy or an ev spirit are thought to be, ætiological factors; and round h comes with his little bag like any other doctor. True th equipment he turns out on the table, is rather differe from that with which Dr. Geoffrey Barber regales prospecti general practitioners at St. Mary's.[2] The outfit of a Nigeria

2. *Lancet*, 1952, i, 495.

medicine man, shown at the exhibition, includes (besides scissors, and materials for dispensing the equivalents—probably—of aspirin or cascara) a bell, the nest of a weaver bird, and an assortment of small animal skulls. Rattles too are popular, and Cetewayo's personal physician habitually carried 13 small horns, and a number of rough knives. These objects are commonly brought round in a wicker basket, but at least one practitioner used a bag composed of a more than part-worn jackal skin, with the head still attached.

Standards of professional integrity sometimes fall rather low, especially among the priests of Shopono—in some parts of Africa the God of smallpox. As so often happens in primitive societies the priests combine their profession with that of medicine, and do very well out of both: not content with holding a monopoly in the treatment of smallpox (by mediating with the god in return for an exorbitant fee) they also claim the property of all who die of it; and are not above furnishing their own epidemics by carrying the virus round in cowrie shells, and leaving it about in other people's houses.

It is a relief to turn from these evidences of malpraxis to a little straightforward surgery. An illustrated account of the cæsarean section seen by Dr. R. W. Felkin in Uganda in 1879, and the very knife with which this successful operation was almost certainly done, show that aboriginals are not always mystical in their medicine. Cupping horns, miniature bows and arrows for venesection, pincers for dentistry, and sharks' teeth beautifully mounted as lancets give a vivid idea of the skilful hands that make and use them. The usual trephined skulls offer their perennial problem to the servants of aseptic surgery.

The centre-piece of the exhibition is a tusk set on a bronze head, and splendidly carved with the ancestors of a king; and round the room are set such masks and figures as puzzle and capture the imagination. Nothing could be more agreeable than the winged top-hatted figure designed by his European authority to scare away spirits; and the seated figure of a woman from the Nicobar Islands is a considerable work of art. But for pure charm the prize must go to the black callipygous lady of unknown provenance—perhaps the Hottentot Venus in person—whose innocent humble face is as haunting as that of the Mona Lisa—and quite remarkably different.

MEDICAL WAR RELIEF FUND

During 1950–51 16 awards were made from this fund, of which 15 were gifts and the other a loan. Of the 15 gifts, 6 were towards the school or university expenses of children whose fathers had been killed in the war, and the remainder were for the maintenance of doctors who have suffered illness attributable to the war, or for other special purposes. Since the fund was started loans to the value of £19,000 have been made. There is still a balance of £15,000 in hand, but it is expected that the calls on the fund, particularly for children's education, will continue. The committee has decided for the time being not to invite further contributions.

BRITISH UNIVERSITIES

The *Yearbook of the Universities of the Commonwealth, 1952*, is the twenty-ninth issue and is published[1] for the Association of Universities of the British Commonwealth (formerly the Universities Bureau of the British Empire). In addition to general information about, and staff lists of, every university in the British Commonwealth, some events of interest during the previous academic year are reported. An appendix includes the five universities of Eire, and another describes Anglo-American academic relations.

THE W.A.M.J.

We welcome the reappearance of the *West African Medical Journal* which has been in abeyance since 1938. The directors of the medical services of the four Colonies sponsor a new 40-page journal which is to be issued quarterly from the University College of Ibadan. The editor, Dr. D. B. Jeliffe, of Ibadan, is to be congratulated on a good first number, to which the African D.M.S. of Nigeria, Dr. S. L. A. Manuwa, writes a foreword. Western medicine is not only acclimatising itself to West Africa but is becoming almost indigenous, and a journal such as this gives expression to the more valuable kind of national endeavour. Some day, no doubt, the *W.A.M.J.* will be printed and produced on the Coast and on African paper, and we hope it will long continue to record things new out of Africa. Orders for the journal (1 guinea per annum, or 6s. for a single copy) should be addressed to Effingham House, Arundel Street, Strand, London, W.C.2, or to the Editor, University College, Ibadan, Nigeria.

MORTALITY FROM GASTRIC CARCINOMA

Prof. Gunnar Nyström,[1] of Uppsala, has lately cast an interesting light on the number of deaths from cancer. Since the beginning of 1948 official Swedish statistics have shown the number of such deaths in people between the ages of 70 and 80, and from 80 onwards; and in 1948 and 1949 deaths after the age of 80 accounted for about one-seventh of all the deaths from cancer. For the City of Stockholm there has been a remarkable fall in gastric-cancer mortality among males. Between 1905 and 1940 this mortality ranged from 55 to 63 per 100,000 population. After 1940 this rate fell rapidly, and in 1945 it was down to 43. For women there has also been a similar fall, though less pronounced. Professor Nyström has explored the possibility that this fall may be due to operative treatment; but he finds that surgeons can claim very little credit for it. In his opinion, it reflects a falling incidence of gastric cancer—a fall that, according to Henschen, may be due to a rising standard of living, with better and more digestible food. Professor Nyström emphasises that generalisations about rising cancer mortality are apt to be misleading if the patients' ages are ignored.

University of Oxford

Dr. Florence B. Seibert of the Henry Phipps Institute, University of Pennsylvania, will deliver a lecture on Tuesday, July 29, at the Dunn School of Pathology on the Isolation of the Tubercle Bacillary Protein Fraction and its Ability to Sensitise Cells.

University of London

At recent examinations the following were successful:

D.P.H.—Mohammad Abbas, Mignon B. S. M. Alexander, P. A. Allsopp, J. D. B. Andrews, C. H. J. Baker, T. D. Blott, W. T. Buckle, L. J. Clapham, James Clarke-Taylor, T. E. J. de Fonseka, W. E. Denbow, N. R. E. Fendall, A. M. Gillespie, G. R. Gunn, A. T. Halliday, C. V. Harries, F. J. W. Hooper, Zein El Abdin Ibrahim, D. N. Keys, H. T. Knights, J. A. H. Lee, J. I. Lesh, J. C. G. Lockyer, Emeric Losonczi, J. F. Lucey, Betty J. McConnell, Sheila C. MacGregor, D. K. MacTaggart, June M. MacTaggart, Sardari Lal Malhotra, Robert Maycock, H. B. M. Murphy, Balbir Ball Greene Nehaul, J. A. B. Nicholson, D. A. Parker, A. G. Poulsen-Hansen, M. J. Rayner, Myrtle V. Richards, J. M. D. Roberts, Kathleen I. Scott, D. F. S. Shaw, J. F. Skone, Frank Summers, V. M. S. Thevathasan, A. L. Thrower, E. H. Todd, J. N. Twohig, A. J. Walker, M. D. Warren, Alfred Yarrow.

D.T.M. & H.—P. A. Cooper, B. O. L. Duke, E. B. Harvey, John Newsome, R. T. Scholes.

Medical Research Council

The council has made the following travelling awards for 1952–53:

Rockefeller Travelling Fellowships in Medicine

Dr. M. de Burgh Daly, lecturer in physiology, University College, London.

Dr. J. E. Hotchin, member of scientific staff, National Institute for Medical Research, London.

Dr. E. L. McDonald, assistant to professor of medicine, Middlesex Hospital, London.

Dr. R. G. Mitchell, lecturer in child health, University of St. Andrews, Dundee.

Dr. N. B. Myant, member of scientific staff, department of clinical research, University College Hospital Medical School, London.

Dr. P. C. Reynell, graduate assistant, Nuffield department of clinical medicine, Radcliffe Infirmary, Oxford.

Eli Lilly Travelling Fellowships in Medicine

Dr. C. J. Earl, junior lecturer, department of chemical pathology, Guy's Hospital Medical School, London.

Mr. P. H. Schurr, senior registrar in neurosurgery, Radcliffe Infirmary, Oxford.

Dr. R. G. White, Freedom research fellow, London Hospital.

Dr. G. M. Wilson, senior lecturer in therapeutics, University of Sheffield, and assistant physician, Sheffield Royal Infirmary.

Dorothy Temple Cross Research Travelling Fellowships in Tuberculosis

Dr. C. N. Hand, lecturer in bacteriology, University of Bristol.

Mr. H. Platt, university research fellow in veterinary pathology, department of pathology, University of Liverpool.

Alexander Pigott Wernher Memorial Travelling Fellowships in Otology

Dr. D. R. Haynes, department of otolaryngology, Johannesburg General Hospital.

Dr. R. F. Naunton, member of scientific staff, Wernher research unit on deafness, Institute of Laryngology and Otology, Royal National Throat, Nose, and Ear Hospital, London.

French Exchange Scholarships in Medical Science (in association with the Centre National de la Recherche Scientifique)

Dr. J. D. Carr, British Empire Cancer Campaign grantee, Poultry Research Centre, Edinburgh.

Dr. M. A. Epstein, assistant pathologist (research), Bland-Sutton Institute, Middlesex Hospital, London.

---

[1] London: G. Bell & Sons. 1952. Pp. 1661. 42s.

[1] *Svenska Läkartidn.* June 13, 1952.

University of Leeds

Dr. Winifred Burbury has been appointed senior lecturer in child psychiatry.

Mr. P. J. Moir has been elected dean of the faculty of medicine for 1952–53 in succession to Prof. J. W. McLeod who is retiring. It is expected that Mr. Moir will give about half his time to the duties of the deanship, which have increased in recent years to such an extent as to require more time than can be given by the head of a university department.

University of Edinburgh

On July 16, the following degrees and diplomas were conferred:

M.D.—* Marion B. Bethune, † J. C. Cruickshank, † J. W. A. Duckworth (in absentia), R. A. K. Harper, Runa B. Mackay; * A. R. Muir, Thakur Ram Nath Parhar, C. H. M. Walker.

* Highly commended. † Awarded medal.

Ph.D. (in the faculty of medicine).—Bruce Cruickshank, Zbigniew Godlowski (in absentia), R. H. Girdwood, Autar Singh Paintal.

M.B., Ch.B.—D. H. Adamson, J. C. Aickin, J. A. Aitken, N. C. Allan, H. C. Allen, Anne J. Anderson, Andrew Armstrong, E. F. Auden, Timothy Awuku-Asabre, W. M. Ayles, J. A. M. Bain, Arthur Banks, F. M. Begg, W. D. Bennett, A. J. Berry, H. S. P. Binnie, Sheila H. Birse, G. C. Biss, Alexander Bisset, Allan Black, J. G. Blyth, Heather Bremner, Alison G. H. Brown, Jean F. Brown, Donald Budge, Douglas Cadger, Helen M. Caldwell, H. A. Campbell, D. I. B. Carrie, T. M. Chalmers, D. G. Chambers, Agnes Clark, H. G. Clarke, Allan Craig, Margaret Cramb, F. M. R. Cranston, G. A. G. Crease, * S. H. Davies, K. J. Dennis, Margaret M. Dewar, Agnes M. Dickson, Andrew Doig, P. H. Dootson, Betty Duncan, J. K. Edwards, W. A. Elliott, E. T. Faunch, William Ferguson, J. A. D. Gillies, Joyce Y. Graham, R. W. Graham, M. J. Grayson, W. M. Haining, Daphne V. M. Halliday, William Harrison, Pamela P. Hartley, G. I. Hendry, Rena E. Hogg, James Hood, Margaret Hope, Agnes C. Howie, Constance C. M. Howie, G. A. Ives, T. P. C. Jameson, V. W. Johnson, S. M. Joubert, Lilias Kilpatrick, Christine C. G. Krause, Mairi H. Lack, J. P. Laidlaw, R. B. Laidlaw, Ann L. Langley, A. W. B. Lawson, W. J. H. Leckie, P. B. Lesslie, C. D. Livingstone, Margaret A. Loraine, I. A. Lowe, G. B. McAulay, H. F. MacConnachie, Alexander McDonald, H. J. McDonald, Hugh Macdonald, Isobel Macdonald, Jean M. Macdonald, Robert Macdonald, G. P. McGovern, D. P. McGowran, Duncan MacGregor, Kathleen L. MacGregor, G. M. McLaren, John Macleod, Murdo Macleod, Inez M. McMurray, John McNae, I. S. McRobbie, R. G. Mahaffy, J. M. Main, J. E. Malcolm, C. M. Manson, T. W. Manson, F. P. S. Marriott, J. A. K. Meikle, K. T. W. Miller, W. H. Morgan, J. K. Morrison, N. M. Munnoch, Dorothy Murphy, P. J. B. Murray, G. J. M. Nairn, W. J. Newlands, Paulette O'Dowda, J. N. Park, Morag Parnell, R. A. Parry, A. B. Partridge, Margaret D. Paton, R. W. F. Paul, W. F. Paveley, William Peter, R. C. Phellas, D. E. B. Powell, H. W. S. Rankin, Jean M. Reid, Kathleen M. Robb, M. K. Robinson, A. I. Ross, I. A. B. M. Ross, T. A. Sanderson, P. D. Sears, Marjorie E. J. Shafto, Doreen W. Shennan, J. P. Shutt, B. C. S. Slater, W. D. Smith, A. K. M. Stewart, F. L. Sturrock, J. H. Tait, D. E. M. Taylor, J. A. Taylor, I. M. Thom, C. H. Thomson, E. D. M. Tod, I. C. K. Tough, G. H. Wallace, G. S. Wallace, Alexander Watt, G. O. Way, D. B. Williamson, J. B. Williamson, A. O. A. Wilson, James Wilson, H. W. Wright.

* Honours.

D.P.H.—E. C. B. Bramwell, Isobel B Drummond, R. R. Gillies, R. S. Hardie, Elizabeth C. Nelson, J. H. Nicolson, Robe Krishava Ramadwar, Shafiqur Rehman, W Shearer, C. E. G. Wickham, I. M. Wood, H. W. Woolmer, E. W. Wright.

D.T.M. & H.—Ahmad Mohamed Ishak El Haddad, D. M. Cameron, D. G. Conacher, Aisha Zaki Shafei Hanno, W. K. Lutterodt, Yahia Marzouk, Hareebrun Bunsee Singh, Chengleput Harikrishnan Sivaraman.

D.Psych.—Beatrice M. Allen, David Satya Nand.

The Cameron prize in practical therapeutics has been awarded to Prof. K. P. Link, PH.D., who holds the chair of biochemistry in the University of Wisconsin, in recognition of his work on anticoagulant therapy.

National University of Ireland

The degree of M.D. has been awarded to Prof. Edward J. Conway, F.R.S.

Royal College of Surgeons of England

A three-dimensional film in colour will be shown at the college, Lincoln's Inn Fields, London, W.C.2, on Thursday, July 31, at 5 P.M., of an operation for Radical Resection for Carcinoma of the Stomach.

Royal Institute of Public Health and Hygiene

On July 16 the Harben medal was presented to Prof. E. C. Dodds, F.R.S., and the Smith award to Dr. Andrew J. Shinnie.

St. Charles' Hospital, London

On Wednesday, July 16, Sir Harold Gillies opened the new accommodation at this hospital for the plastic unit. The new unit, which is to bear his name, is in direct continuity with the first plastic unit which he established at the hospital. It includes two new wards

Research Board for the Correlation of Medical Science and Physical Education

The William Hyde award for 1950 (£300) has been given to Dr. R. W. Parnell, of the Institute of Social Medicine, Oxford, in recognition of his work on the application of special physical measurements (*somatotyping*) to students in Oxford.

Postgraduate Course in Public Health Engineering

Enrolment is now going on for the 1952–53 course in public health engineering, given jointly by the Imperial College of Science and Technology and the London School of Hygiene and Tropical Medicine. Further details may be had from the deputy registrar, City and Guilds College, Exhibition Road, London, S.W.7.

Leeds Medical School Dinner

The annual dinner of past and present students of the Leeds School of Medicine is to be held on Nov. 28 at the Hotel Metropole, Leeds.

Stability of the Family

A conference on this subject is to be held in Oxford between Sept. 8 and 13 by the International Union of Family Organisations. Further information may be had from the hon. secretary of the British committee, c/o British Social Biology Council, Tavistock House South, Tavistock Square, London, W.C.1.

Summer School in Health Education

The Central Council for Health Education is holding a course at St. Osyth's College, Clacton, from Aug. 6 to 16. The speakers will include Prof. Fraser Brockington, Sir Allen Daley, Dr. Richard Schilling, and Dr. A. R. Harrison. Further particulars may be had from the medical director of the council, Tavistock House, Tavistock Square, London, W.C.1.

Biology as a Career

The Institute of Biology is holding a one-day discussion on this subject in Birmingham on Oct. 4, at which Sir Harold Himsworth will speak on Careers in Medical Research. Further particulars may be had from the general secretary of the institute, Tavistock House South, Tavistock Square, London, W.C.1.

Manchester Royal Infirmary Old Residents' Club

The 11th reunion of this club will be held at the Midland Hotel, Manchester, on Saturday, Oct. 4, 1952, in the bicentenary year of the infirmary. Further particulars may be had from the honorary secretary of the club at the Manchester Royal Infirmary.

Fellowship in Virology

The British Memorial Fund in Victoria, which was set up as a gesture of "loyalty, gratitude and affection" to the British people in recognition of their rôle in the second world war, is offering a fellowship in virology to a British graduate.

The fellowship (£A1000) provides for ten months' study in Victoria and covers all travelling and living-expenses during the period. It is open to graduates in medicine or science, under 35, who contemplate a career in research or teaching or who have already had some research experience in microbiology or biochemistry. Study will be at the Walter and Eliza Institute Hall, Melbourne, chiefly in the field of virus diseases. Further details can be obtained from Sir John Lienhop, Victoria House, Strand, London, W.C.2. Applications will be received during the next four weeks.

CORRIGENDUM: *National University of Ireland.*—In announcing the honorary degrees lately conferred by the university (*Lancet*, July 19, p. 151) the names of the sponsors were inadvertently included. The list should have read as follows:

LL.D.—Prof. E. P. McLoughlin, Dr. A. W. S. Sichel.

D.Litt.—Mr. William Doolin.

D.Sc.—Sir Henry Cohen (in absentia), Sir John Parkinson.

M.D.—Major P. J. Delaney, Sir Stewart Duke-Elder, Sir John McNee, Dr. Angus Macrae.

M.D.S.—Dr. J. P. Walsh.

On July 19, Major A. B. Kinnier-Wilson, late R.A.M.C., won the Queen's prize at Bisley.

Sir James Learmonth has been elected a foreign correspondent of the National Academy of France.

Dr. F. Avery Jones will be away on a Nuffield Foundation lecture tour in Australia and elsewhere from Aug. 3 to Nov. 3.

THE ARTERIAL LINING*

J. B. Duguid
M.D. Aberd.
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF DURHAM

To anyone who has studied the vast literature on arterial disease it must appear that every conceivable aspect has been covered, and that the principles laid down nearly a hundred years go, having stood the test of time, are beyond question. But I believe this to be wrong; and I would like to submit a conception which, though not new, has been entirely overlooked in the writings of the past century. We have been brought up on the cellular theory, a convenient formula by which to explain the development of morbid processes; but most morbid histologists must, I think, have felt from time to time that it did not quite fit some of the changes they have been called on to interpret. To me atherosclerosis has been a case in point.

PATHOGENESIS OF ATHEROSCLEROSIS

About the middle of last century von Rokitansky attributed atheroma of the aorta to the deposition of layers of fibrinous material on the inner surface of the vessel, the fibrin later undergoing fatty change and sometimes softening. He thus viewed the arterial thickenings as products of the blood. Somewhat later Virchow elaborated his cellular theory which embodied the principle that all morbid structures consisted of cells which were derived from pre-existing cells; and in accordance with this he held that atheromatous thickenings were the products of the connective-tissue cells of the arterial intima. On these two conflicting ideas there ensued a controversy in which Virchow used an argument which has, I think, done lasting harm. He argued that since the thickenings were subendothelial—i.e., external to the endothelial lining—they could not be surface deposits. He thus referred to the endothelium as if it were a fixed landmark by which the tissues of the vessel could be identified, and in so doing established a misconception which has to this day restricted our approach to arterial disease. We are still taught to regard all parts of the vessel wall external to the endothelial lining as belonging to the vessel not only structurally but also as regards development; and this is easily shown to be wrong.

One has only to study a canalised thrombus in a coronary artery (Duguid 1946) to see that a new endothelial lining develops wherever a new channel is formed, and that where this has occurred the thrombus is external to it. Moreover, when the thrombus becomes organised it forms a fibrous mass which is continuous with the intima, and sometimes quite indistinguishable from it. In short the mass which was originally formed in the blood-stream becomes a part of the vessel wall. The same is seen in mural thrombi, which are far commoner (Duguid 1948, 1949) than we have been led to imagine. They also become covered by endothelium and are thus incorporated in the vessel walls, with the result that when they are organised they form fibrous thickenings of the intima. Moreover, they undergo fatty change; and there can be little doubt that some of the lesions we have been accustomed to classify as atherosclerosis have been of this nature. The same process has been recognised in atherosclerosis of the renal artery by Heard (1949) and in the formation of fibrous thickenings in the mitral valve by Magarey (1951).

Experimental confirmation of the existence of this process can be obtained by inducing arterial thrombosis in animals. If one inserts a silk thread into the femoral or carotid artery of a dog, passing it along the lumen for a short distance and out again, a thrombus forms and in two or three weeks is incorporated in the vessel wall as a fibrous thickening. The same effect can be produced by pricking the central artery of a rabbit's ear. More striking confirmation has been provided by Harrison (1948) and by Heard (1952) who injected particles of fibrin into the veins of rabbits and showed that the particles lodging in the smaller pulmonary arteries were converted into fibrous thickenings of these vessels, producing the morbid appearance we associate with pulmonary hypertension. Another confirmation has recently been provided by Rannie (1951) in relation to experimental cholesterol lesions in rabbits. In the development of these lesions Leary (1949) visualised an active penetration of the endothelium of the arteries by cholesterol-bearing phagocytes which circulate in the blood, but Rannie has produced evidence that the phagocytes are merely deposited on the surface of the arteries and in due course covered by a newly formed endothelial layer so that they are passively incorporated in the intima in the same way as mural thrombi.

Thus Virchow, in putting forward his cellular theory against the thrombosis hypothesis of Rokitansky, overlooked one fundamentally important principle—namely that the endothelial lining of the vessel is an adjustable structure. One of its functions is to rearrange itself so that any solid mass adhering to the internal surface of a vessel is covered and becomes part of the vessel wall. Neglect of this principle has undoubtedly retarded progress in the pathology of arterial disease.

DEVELOPMENT OF HYALINE CHANGES IN ARTERIES

It may of course be argued that the organisation of a thrombus is itself a manifestation of cellular pathology, the thrombus being colonised by cells from the adjacent intima and ultimately replaced by them or their products; but a study of mural thrombi will show that this is by no means the whole sequence. When a mural thrombus becomes incorporated in an arterial wall it may not immediately be invaded by capillaries and connective-tissue cells, or attacked by macrophages, as in the classical process of organisation which we have been taught to visualise. Instead it undergoes a gradual metamorphosis which has some interesting features. First its fibrin loses its characteristic fibrillary structure, and also its specific staining properties, so that it is no longer easily identifiable. In time it becomes condensed and more or less homogeneous, taking a deep pink stain with eosin and having that appearance to which the terms "hyaline" and "fibrinoid" have been applied. Ultimately it may be invaded by connective tissue cells and transformed into fibrous tissue; but it is the intermediate hyaline stage which is on the whole the most prominent, and there is little doubt that, in this stage, old mural thrombi have frequently been mistaken for degenerations of the intimal connective tissues. (Here I would emphasise the importance of using frozen sections in a study of this kind, since dehydration and paraffin embedding seems to obscure the finer details of these structures.)

Thus Rokitansky was in a large measure correct in his thrombosis hypothesis, but the hypothesis has been forgotten and we have been so influenced by the cellular theory as to be blinded to the possibility of an alteration in the appearance of an artery meaning anything but a change in its original constituents. With recognition of the existence of a process by which deposits in the blood-stream are converted into thickenings of the vessel walls, a fresh approach to the problem of arterial disease opens, and we must now review the histology in the light of it.

---

* Abridged from the Kettle memorial lecture delivered at Cardiff on Nov. 23, 1951.

HYALINE CHANGES IN THE ARTERIOLES

A form of arterial disease in which hyaline change figures especially prominently is the arteriolosclerosis seen in the kidneys, spleen, and other organs in hypertension and in diabetes mellitus. This lesion consists of a hyaline thickening of the walls of the arterioles with narrowing of their lumina, and the orthodox interpretation seems somewhat paradoxical. The hyaline thickening has been taken to be a degeneration, but it is difficult to see how a degeneration could be associated with narrowing. When it is remembered that arterioles are subject to an internal pressure of blood equivalent to 20 mm. Hg or more, a degeneration would be expected to lead to weakening and dilatation, and the fact that they are consistently narrowed seems to suggest that there may be some other explanation. Since hyaline change in the larger arteries can be produced by mural thrombi it seems not unreasonable to suspect that a similar process may be involved in arteriolosclerosis, and with this in mind G. S. Anderson and I have reviewed the histology of hypertensive and diabetic kidneys. Our findings (Duguid and Anderson 1952) seem to support the suspicion.

In the typical hyaline arteriolosclerosis, as seen for example in the afferent arterioles of the renal glomeruli, a layer of hyaline substance, usually much thicker than the original vessel wall, surrounds the narrow lumen and displaces the medial coat outwards. In the vast majority of instances its inner surface is lined with endothelium, so that it has every appearance of being a part of the intima; but if one searches carefully through the more severely affected kidneys one will usually find exceptions in which the hyaline layer is exposed to the blood-stream. In such instances its internal surface is usually ragged, and there may be loose fragments of hyaline substance more or less mixed with the elements of the blood, while sometimes the lumina are actually plugged with the substance. Such formations are particularly well seen in cases of malignant nephrosclerosis where some of the thickenings may be composed of newly formed fibrin, or fibrinoid material as it is called, and where the lumina are represented by irregular clefts entirely devoid of endothelium.

These appearances lend some support to the suspicion that the so-called hyaline degeneration is actually a deposit of fibrin or other coagulum in the lumina of the vessels; for they are what would be expected in the early stages of such a process, before the new endothelial lining has formed. I realise of course that these occasional findings prove nothing—histology seldom provides decisive evidence on a question of this kind—but it must be remembered that the orthodox interpretation, against which they have to be weighed, is likewise without proof. There is no reason to believe that the hyaline substance represents a degeneration of the tissues beyond the fact that it looks like one under the microscope, and then only provided the narrowing is ignored. When the narrowing is taken into account the weight of evidence seems to be all in favour of the deposit hypothesis, for it is obvious that a deposit in the blood-stream must narrow the lumen of the vessel from the outset, whereas a degeneration, which must interfere with the strength and resilience of the wall, would be more likely to lead to aneurysm. There is therefore, to say the least of it, some reason to doubt the long-accepted interpretation of these lesions and to throw the matter open for reconsideration from a fresh viewpoint.

At the present time there is little satisfactory information as to the nature of the hyaline deposits, if such they be. It is perh[illegible] that some of the arteriolar thickenings in [illegible] consist of fibrin, whereas others, [illegible] ion, are hyaline, because it suggests that here, as in the aorta, fibrin may in time form hyaline substance. This does not however imply that all hyaline substance may arise in this way. One often sees small masses of eosinophil coagulum mixed with the blood in the arterioles in such a way as to suggest that protein substances other than fibrin may be precipitated in the circulation and choke the smaller vessels. No doubt with newer methods of histochemical analysis these substances will in due course be identified, but it should be borne in mind that their identification will be of doubtful value so long as their relations to the existing tissues remain uncertain.

NATURE OF THE CONNECTIVE TISSUES

The importance of this latter consideration becomes evident when we refer to some of the problems of connective-tissue change which are now occupying attention. There is for example the question of the ageing of collagen. It has been suggested that the hyaline or fibrinoid change seen in the arteries of old people represents an ageing of the collagen fibres, and attempts have been made to determine the nature of this change. If, however, the hyaline substance is, as I suspect, not collagen but altered fibrin, then the results of such investigations may only lead to further misinterpretations. Similarly the conception of the so-called collagen vascular diseases is involved. This group of diseases, which includes disseminated lupus erythematosus and polyarteritis nodosa, is said to be characterised by certain alterations in the extracellular connective tissues, and hyaline or fibrinoid changes in the renal arterioles are cited as examples. These have been referred to as chemical or physical alterations either of the connective-tissue fibres or of the interstitial ground substance, and special efforts have been made to determine their nature in the hope that some light might be thrown on the development of connective tissue; but if they are altered mural thrombi or some other coagulation product we are again in danger of being misled. Obviously no conclusions as to the nature or development of connective tissue can be based on these arterial thickenings until we know exactly what developmental relation they bear to the vessel walls. It will readily be seen that the same considerations must apply to the non-vascular collagen diseases and any other conditions in which fibrinoid change figures.

CONCLUSIONS

These tentative interpretations of the pathogenesis of atherosclerosis and hyaline arteriolosclerosis have been put forward to show that the orthodox views are not the only possible ones. I do not wish to press them, but rather to bring out the important principle on which they are based. In the past our views on arterial disease have been limited by the notion that all new tissues are the products of pre-existing cells, and that any increase in the thickness of a vessel signifies either swelling or proliferation of its tissues. We must now recognise that the extracellular tissues are not necessarily subject to any such law. The fact that the arterial lining is a labile structure makes it possible for solid matter forming in the blood-stream to be added to the body tissues, and that fact has I think been proved beyond any shadow of doubt.

THE TREND OF SERUM-CHOLESTEROL LEVELS WITH AGE

ANCEL KEYS
Ph.D.
DIRECTOR OF THE LABORATORY OF PHYSIOLOGICAL HYGIENE, UNIVERSITY OF MINNESOTA; SENIOR FULBRIGHT FELLOW AT OXFORD UNIVERSITY, 1951–52

FLAMINIO FIDANZA VICENZO SCARDI
GINO BERGAMI

From the Institutes of Physiology and Biochemistry of the University of Naples and the Laboratory of Human Nutrition of the University of Oxford

It is increasingly evident that the largest, and perhaps the most difficult, health problems in the Western World are presented by those non-infectious disorders seemingly associated with ageing. It would be over-sanguine to hope for indefinite postponement of ageing in general, but people do not all age at the same rate, and even in the same person there may be well-marked differences in the ageing of different tissues and organs. Not only the relatives and the family physician are outraged when, for example, myocardial infarction strikes a man in full physical and mental vigour, and it is small consolation to have the pathologist report that the victim had the coronary arteries of an old man. Besides the social loss, the medical scientist is chagrined to have no better clue to physiological age—in this case of the arteries—than the number of years from birth.

This justifies, therefore, the most vigorous efforts to explore measurable human characteristics that change with age after the years of growth, particularly if these may be associated in any way with a morbid process, such as atherosclerosis, which tends to anticipate general ageing. So we were interested to find, in a study of clinically healthy men in Minnesota, a distinct difference in the average serum-cholesterol levels between young and middle-aged men.[15] That the serum-cholesterol level is significant in relation to the development of atherosclerosis is now, of course, well established.[5 6 11 12 14 16 17]

PREVIOUS STUDIES

In an expansion of the research in Minnesota observations on 1492 clinically healthy men showed a steady rise in the average serum-cholesterol level from the late 'teens until the mid-50s, the average annual increment being about 2·3 mg. per 100 ml.[20] The analysis of data from smaller series of men studied in New York,[23] southern Minnesota,[1] San Francisco,[4] Boston,[8] and Denmark,[21] showed reasonable agreement. In 46 relatively young men in England there was a mean annual rise of 1·7 mg. per 100 ml.[25]

Though all of these studies show much the same age trend, they are also all in agreement that there is much variation between people of the same age, the standard deviation of the mean being about 30–45 mg. per 100 ml. In other words, the standard deviation of serum-cholesterol for a group of men of identical chronological age is equivalent to something like plus or minus 15 years of age. As the age trend of atherosclerosis varies similarly from one person to another, it is tempting to suggest that the serum-cholesterol level may be a more useful index of vascular age than of mere years. In any case, it is essential to inquire into other factors than age which affect the serum-cholesterol level.

In cross-sectional surveys we found no relation at any age between the serum-cholesterol level and the habitual dietary intake of cholesterol[15 19] and this has been confirmed by others.[9 28] In controlled experiments lasting some months it was found that drastic changes in the cholesterol intake of man are without effect on the serum-cholesterol level if the intake of calories and fats is constant, but that changes in the intake of fat have a profound effect.[18 19] Well-marked changes in the serum-cholesterol level appear when the intake of fat is substantially altered, even when both calorie and cholesterol intakes are constant.[13 19] For example, in healthy men there was an average difference of 64 mg. of cholesterol per 100 ml. of serum in alternating periods of a month each on daily intakes of 11 g. and of 110 g. of vegetable fat, the diet being at all times devoid of cholesterol and animal fat. In identical experiments, in which at all times the diet provided about 700 mg. of cholesterol daily, the serum-cholesterol level averaged 61 mg. per 100 ml. less on the low-fat diet than on the intake of 68 g. of fat (A. Keys and J. T. Anderson, unpublished). The response of serum-cholesterol to diets low both in fats and cholesterol[3 26] is therefore explained by the change in fat, the dietary cholesterol being unimportant.

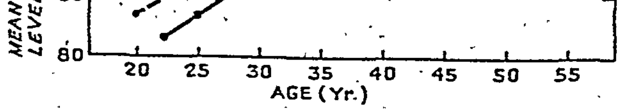
Now, in those countries in which the cholesterol-age trend has been studied so far, the national dietaries are similar as regards the proportion of total calories supplied from all kinds of fats. In 1949 fats supplied about 38% of the calories in the United States, 34% in Denmark, and 32% in the United Kingdom.[7] Studies of actual intake in working-class families in England gave an average of 35% of calories from fats in 1949, and in 1947 (the low point in supplies of fat in recent years) the average for the English families surveyed was 32%.[22] Our cholesterol data so far, then, all pertain to regions of high-fat diets.

STUDIES IN NAPLES

We have now been able to study this question in Naples, where the intake of fat is much less. For the whole of Italy in 1949 the average was 20% of calories from fats,[7] and in the men surveyed by us in Naples we found the same value.

The Neapolitan subjects were 84 clinically healthy men, aged 18–54 (average 35·5), employed by the City of Naples as firemen and as *vigili annonari* engaged on inspection and auxiliary police tasks. To assure comparability with the Minnesota study, we were at pains to use the same cholesterol method[20] in all details and brought the essential apparatus, as well as pure cholesterol standards and acetic anhydride, direct from Minneapolis. Each serum sample was analysed in duplicate, and satisfactory repeatability was obtained. The men were taken for study in a random sequence of ages.

From preliminary inspection of the data it was clear that the Naples data departed widely from a simple linear relation between age and serum-cholesterol level over the entire age-range; so the expedient was adopted of analysing the data for restricted successive age-



Mean serum-cholesterol levels in healthy men in Naples and in Minnesota. For each city the values are expressed as percentages of the average for age 35 in that city. The numbers of Neapolitans in each age-group were as follows: aged 18–25, 13; 21–30, 23; 28–34, 24; 32–39, 25; 37–44, 24; 43–49, 24; and 44–54, 18. The values for Minnesota were computed from data of Keys et al.[20]

groups. The main features of the findings are shown in the accompanying figure.

Up to about the mid-30s the Neapolitans had a similar age trend to that found in Minnesota and elsewhere, but thereafter they did not show any further rise. Whereas in Minnesota there is an average rise of about 40 mg. of cholesterol per 100 ml. of serum from age 35 to age 50, in the Neapolitans the average serum-cholesterol was a plateau over those years. Statistical analysis (see table) showed that the difference between the two population samples is highly significant. The mean annual increments were computed as the slopes of the least-squares regression lines fitted to the data over age-groups in which there is no significant curvilinearity. There is a highly significant difference ($t = 4{\cdot}3$, $t_{0{\cdot}001} = 3{\cdot}3$) between the slopes in the years between 30 and 48, but up to the early 30s the slopes were not significantly different. Beyond age 30 the Naples data show no significant departure from zero age trend.

ANNUAL INCREMENTS OF AVERAGE SERUM-CHOLESTEROL LEVEL IN CLINICALLY HEALTHY MEN OF DIFFERENT AGES IN NAPLES AND IN MINNESOTA

Region	No. of men	Age (yr.)		Rise of serum-cholesterol level per year (mg. per 100 ml.)	
		Mean	Range	Mean	Standard error
Naples ..	58	38·4	30–48	0·37	0·87
Minnesota ..	116	37·3	30–45	3·63	0·69
Naples ..	40	27·9	18–34	3·10	1·00
Minnesota ..	1172	23·7	17–45	2·29	0·18

It would be unwise to draw sweeping conclusions from the Naples findings about the relation between diet and the incidence of atherosclerosis. Other factors besides those considered here require attention, and direct evidence on the incidence of atherosclerosis is lacking. On the latter point we have only the unanimous judgment of the local physicians that coronary-artery disease is less common in Naples than in the United Kingdom and the United States, except, perhaps, in the rich people, who were not represented in our sample. It should be added that coronary-artery disease is understood and recognised by these physicians in the same way as in the United Kingdom and in the United States.

But several facts are clear. The Neapolitans live on a diet far lower in fats than in the United States, Britain, and northern Europe, and they have always so subsisted. The diet is also relatively low in cholesterol and in animal proteins. In spite of these differences the serum-cholesterol level is not low in the young men, and the age trend in early manhood is much the same as in men in the other areas studied. But in the years when, in other areas, a major development of atherosclerosis occurs, the Neapolitans differ in the absence of the expected continued rise in the blood-cholesterol level. So far we can find no reasonable explanation other than the dietary difference. The climatic factor seems unimportant in view of the differences of climate between Minnesota, California, Massachusetts, and Denmark, in all of which the age trend continues at least into middle age. Possible differences in physique and relative obesity [15 25] are currently under scrutiny, but at best only a part of the discrepancy could be explained on this score; the Naples men were neither unduly thin nor unduly fat and were not remarkable in somatotype.

There are a few published reports on serum-cholesterol levels in populations which subsist on diets differing from the U.S.-U.K. pattern in their fat and cholesterol content, but none of these is satisfactory for the present analysis. In India various results suggest a low average level of cholesterol in "healthy" persons,[2 10] but the methods used are faulty, and age was not considered. A recent study [27] on Alaskan Eskimos ignored age but concluded that the serum-cholesterol level is high and that this is related to the carnivorous diet; the averages cited, however, are not unusual for adult populations studied elsewhere.[20] It has been reported that six days' subsistence on fatty pemmican raises the level of all serum-lipids in Canadian Eskimos.[24]

SUMMARY AND CONCLUSIONS

In populations habitually subsisting on relatively high-fat diets—e.g., in the United States and most of northern Europe—the serum-cholesterol level tends to rise steadily with age from adolescence through middle age.

In 84 clinically healthy men in Naples, of ages ranging from 18 to 54, the serum-cholesterol level conformed to the U.S.-U.K. age trend to the early 30s but did not increase thereafter.

The Neapolitans, like most Italians, have a diet which is low in fat, and the peculiarity of their cholesterol-age trend is ascribed to this.

These facts probably have a bearing on the development of atherosclerosis and the incidence of coronary-artery disease.

We are grateful to Prof. Ferruccio di Lorenzo for invaluable coöperation in providing both subjects and clinical assistance; to Mrs. Margaret H. Keys for much aid in the cholesterol determinations; and to Dr. A. del Vecchio for willing help. Our greatest obligation, of course, is to the subjects whose voluntary coöperation was the basis of the work. The investigation was aided by a research grant to one of us (A. K.) from the National Dairy Council acting on behalf of the American Dairy Association.

"The scientist, conscious of possessing a key that does open the locked doors, of the world-wide agreement of his colleagues, and of new secrets being wrested from Nature almost daily, is likely to ask, 'What have these philosophers ever *discovered*?' It is part of the philosopher's business to listen to criticism with patience and attention; but there are limits even to a philosopher's patience; and there is an immediate answer to this one, which I cannot refrain from offering. The philosophers have discovered science."—Prof. JOHN MACMURRAY, *Univ. Edin. J.* Summer Number, 1952, p. 87.

TORSION OF THE TESTIS AND ITS APPENDIX

ANTHONY J. WALTON
M.B. Camb., F.R.C.S.
SENIOR ASSISTANT TO THE SURGICAL UNIT, LONDON HOSPITAL

TORSION of the testicle or one of its appendages is still regarded as very rare. I believe, however, that it is by no means so rare as is taught, and that many cases diagnosed as acute epididymo-orchitis are in fact cases of torsion. This particularly applies to boys about the age of puberty and younger.

The first case was published in 1840 by Delasiauve. In 1907 Rigby and Howard described 9 cases seen at the London Hospital and referred to 40 examples in the literature. In 1946 Riba and Schmidlapp described 5 cases and stated that 489 had been published up to 1943. In 1928 Roche reported 3 cases seen by himself within five weeks. Rigby and Howard (1907) and Roche (1928) dealt in detail with the ætiology, symptoms, signs, and diagnosis, and there is in fact nothing to add to their description. They emphasise the frequency with which torsion of the fully descended testicle is diagnosed as acute epididymo-orchitis, and it is the frequency with which this mistake is still being made that makes me think that there is a place for a further paper on the subject.

MATERIAL

I have seen 11 proved cases, but 3 of these have been reported by Kennedy (1948) in his series of 11 cases of torsion of the testicle (not including torsion of the testicular appendix) seen at the London Hospital in twenty years ending in 1948. I have now collected a further 8 cases at the same hospital since 1948. These 8 cases, in 1 of which there was subsequently torsion on the opposite side, together with 2 cases of torsion of the hydatid of Morgagni and a case of torsion of the testicle treated elsewhere, form the substance of this paper. An example of torsion of a boy's only testicle eleven years ago, the other having been removed a year previously for the same condition, is not included, because the notes are not available.

Brief histories of 3 of the 11 cases are given below, and a summary of the remaining 8 is given in the accompanying table.

ILLUSTRATIVE CASE-RECORDS

Case 1.—A boy, aged 11, was first seen on May 15, 1947, with twelve hours' history of sudden pain in the left groin. He had not vomited.

On examination his temperature was 98°F and pulse-rate 72. His left testicle was not felt in the scrotum. There was an extremely tender swelling at the left external inguinal ring, where the overlying skin was red. A diagnosis of torsion of an undescended testicle was made, and he was admitted to hospital.

Operation (three hours later).—Under anæsthesia the testicle was felt in the scrotum and the inguinal swelling had disappeared. Through a left inguinal incision the testicle was delivered, and the tunica vaginalis was opened. It contained a little bloodstained fluid. The hydatid of Morgagni, which was twisted and gangrenous, was removed.

The boy made an uninterrupted recovery and was discharged on the tenth day.

Case 2.—A man, aged 32, was admitted on Nov. 1, 1949, with twelve years' history of recurrent attacks of mild pain and swelling of the left testicle, lasting for an hour or two and occurring about twice a year. Five years ago he had had severe pain in the left testicle. He was sent to hospital with the diagnosis of torsion of the left testicle, but the pain and swelling disappeared in the ambulance. For five hours he had had severe pain and swelling in the left side of the scrotum. He felt ill and vomited. There was no disturbance of micturition and no urethral discharge.

On examination the patient had a temperature of 97°F and pulse-rate 92; he was slightly shocked. The left side of

SUMMARY OF OTHER CASES

Case no.	Age (yr.)	Side	Previous attacks	Duration of present attack	Symptoms, &c.	Temp. (°F.)	Vomiting	Signs	Findings at operation	Operation
4	8	L	Intermittent for 3yr.	5 days	Severe pain in left testicle; off food	98·0	Nil	Tender swelling at external inguinal ring; skin red	Torsion of hydatid of Morgagni	Excision
5	$1\,{}^{7}/_{12}$	L	—	24 hr.	Brother tried to lift by scrotum; developed retention; scrotum red and swollen	98·0	Nil	Swollen red scrotum; skin puckered posteriorly	540° anticlockwise twist; testicle gangrenous	Orchidectomy
6	6	L	Intermittent attacks for a month	18 hr.	Severe pain in left testicle, which swelled	100·1	Nil	Testicle 4 times normal size; skin red but not tender	180° clockwise twist; gangrenous	Orchidectomy
7	13	L	—	4 days	Slight pain on playing football, worse next day, swelling testicle	100·0	Nil	Red swollen œdematous scrotum	Gangrenous. Long mesorchium	Orchidectomy
8	21	L	2 years ago testicle swollen and painful for 1 hr.	5 hr.	Awoken by severe pain	99·4	Nil	Testicle 2 or 3 times normal size, but 1 hr. later normal except for flaccid hydrocele	Long mesorchium (operation 5 days later)	Orchidopexy
9	12	R	—	3 days	Pain and swelling, unable to sleep	99·6	+ +	Red swollen scrotum	Intravaginal twist round lower pole	Orchidectomy
		${}^{11}/_{12}$ later L	—	5 hr.	Mild pain on left side	98·0	Nil	Swollen, untwisted while being examined	Epididymis attached to lower pole only	Orchidopexy
10	2	L	—	12 hr.	Mother noticed tender swollen shiny testicle	97·0	Nil	Four times normal size, shiny, red, and hot	90° twist through upper pole	Orchidopexy
11	42	L	Several milder attacks	3 days	Painful lump in left groin	98·0	Nil	Swelling over external inguinal ring; œdematous skin	Gangrenous undescended testicle	Orchidectomy

his scrotum was swollen and œdematous, with puckered skin. He was admitted to hospital.

Operation (three hours later).—While the patient was being shaved under anæsthesia, the testicle suddenly twisted into its normal position and the swelling disappeared. Through an inguinal incision the testicle was delivered and the tunica vaginalis was found to contain a few ounces of bloodstained fluid. The testicle was congested but viable. The parietal layer of the tunica vaginalis was excised, and the tunica albuginea was sutured to the areolar tissue of the scrotum. The patient was discharged on the ninth day.

Follow-up.—He was last seen on Nov. 1, 1951, when he had had no further pain or swelling of the testicle, which was of normal size and consistence. Testicular sensation was present.

Case 3.—A boy, aged 16, gave a history of having had a sharp pain in his left groin four weeks earlier. This had eased, leaving a dull ache. Two days later the pain had become more severe, and he had vomited. A swelling in the left side of his scrotum was noted, but his right testicle could not be palpated. His temperature was 102°F. Three days later the swelling increased to "the size of an orange" and was extremely painful. Acute epididymo-orchitis had been diagnosed and treated with sulphonamides without improvement, until a week before admission the swelling subsided and the pain disappeared.

On examination the temperature was 98°F and pulse-rate 80. The right testicle was felt just outside the external inguinal ring. On the left side there was a swelling 2 in. in diameter. The epididymis could not be palpated separately from the swelling.

Operation (Feb. 9, 1950).—Mr. Charles Donald delivered the testicle through a left inguinal incision. It had twisted 180° in a clockwise direction. It was removed and a right-sided orchidopexy was performed.

ÆTIOLOGY

Maldescent

The earlier papers said that most cases were associated with maldescent. There is a simple explanation for this. If the testicle lies in or near the inguinal canal, the patient will present with localised pain, sometimes referred to the abdomen, and a tender irreducible swelling in the groin; often there is vomiting. Such cases are almost indistinguishable from strangulation of an inguinal hernia (so often associated with maldescent), and operation is almost certainly advised.

When the testicle is lying in the scrotum, the signs closely resemble those of acute epididymo-orchitis, and conservative treatment is often recommended.

In the present series all but case 11 concerned fully descended testicles.

Anatomical Anomalies

Far more important is the normal anatomy of the testicle, tunica vaginalis, epididymis, and cord. It is agreed that in all examples of torsion of a fully descended testicle there is some anatomical abnormality. The well-known anomalies are as follows:

(*a*) *Intravaginal epididymis.*—In the normal testicle there is a wide bare area behind the epididymis where the visceral layer of the tunica vaginalis is reflected to form the parietal layer, leaving only a small part of the epididymis in the vaginal sac. As Roche (1928) pointed out, the normal relationship is similar to that of the ascending colon to the peritoneum: there is no mesentery. In many cases of torsion there is a mesentery. This anomaly was well seen in cases 8 and 9.

(*b*) The epididymis is attached at the upper or, more commonly, the lower pole only and passes straight back into the vas.

These, I believe, are the common abnormalities. Roche (1928) described others and emphasised the anchoring effect of the entering blood-vessels. The internal spermatic artery is attached not only at the upper pole but also by branches entering the whole posterior margin. These and the artery to the tail and body of the epididymis will counteract any tendency to rotate round the main pedicle (the internal spermatic artery).

The great majority of torsions are intravaginal and some writers deny the existence of an extravaginal torsion. Campbell (1948), however, reporting 2 cases which occurred on the first day of life, states that both were examples of an extravaginal twist, and his photographs show that this is certainly so.

Trauma

What actually starts the twist seems to be quite unknown. In some cases there has been, as in case 5, a most definite insult to the scrotum, but in many others the torsion develops at rest or even in sleep.

Age

Although the condition has been described in the elderly, it is commonest at about puberty. In this series the ages were 19 months, and 2, 6, 8, 11, 12, 13, 16, 21, 32, and 42 years. The youngest patients in the previously published cases were a child aged 4 hours (Taylor 1897) and Campbell's 2, which also had torsion on the first day of life.

Side

It is curious that in this series the left side was involved in 10 of the 11 cases (in 1 case torsion was bilateral). Roche's 3 cases were left-sided, and in Kennedy's series 8 of 11 were on the left. Aird (1949) states that the right side is involved more often in the proportion 7 : 5, but Kennedy (1948) cites Wallenstein and Abeshouse as having collected 144 right-sided and 142 left-sided.

SYMPTOMS

Pain is a constant feature and is usually of sudden onset. Vomiting is often present, but in this series it was noted in only 4 cases. The pain is referred to the scrotum or the groin according to the site of the testicle. It may be referred to the lower abdomen. It may increase in intensity for a day or two and then gradually subside. Should spontaneous correction take place, there is dramatic relief. Sometimes (cases 2, 4, 6, 8, and 11) there is a history of previous milder attacks.

Difficulty of micturition has been reported in some series. Rigby and Howard (1907) reported that 1 of their patients needed catheterisation, and in the present series the mother of the child aged 19 months noticed that he seemed to be unable to void his urine.

PHYSICAL SIGNS

The signs vary according to whether the testicle is fully descended or not. If the testicle is *in the scrotum*, the overlying skin on that side is red, œdematous, and tender. The scrotal skin may be tethered to the underlying structures. This has been described as Dillon's sign. Extreme tenderness may make precise palpation very difficult, but even under anæsthesia it is usually impossible to distinguish the epididymis from the body of the testis.

In the early stage the patient may be mildly shocked, with a subnormal temperature, as in case 2. More often there is pyrexia; in case 3 it was reported to have been 102°F.

If the testicle is undescended but lying at or near the external inguinal ring, the signs will closely resemble those of a strangulated hernia. As in either event operation is urgently called for, distinction between the two is less important.

In case 1 the left testicle could not be felt in the scrotum, and it must be supposed that pain had elicited a violent and prolonged cremasteric reflex. The parents displayed an astonishing ignorance as to whether the testicle was descended or not.

DIFFERENTIAL DIAGNOSIS

When the testis is not felt in the scrotum, it is extremely difficult to distinguish torsion of an undescended testicle from a strangulated inguinal hernia. If the overlying skin is red and œdematous, it is far more likely to be a case of torsion, for with a strangulated hernia this would be a late sign in a desperately ill patient or (as I have twice seen) due to a foreign body ulcerating through the loop of bowel in a hernial sac. In either event operation is called for.

It is when the testicle is fully descended that mistakes are so often made. All the patients in this series with normally descended testicles, except case 2, were at some stage diagnosed as epididymo-orchitis. I think that, if the following points are borne in mind, error can be avoided:

Age.—Apart from the complication of mumps, epididymo-orchitis must be very rare below the age of 18. Dix (1931) states that cases diagnosed as epididymitis in children are probably examples of torsion of the appendix of the testis. I should add here that it is usually impossible to distinguish between cases of torsion of the testicle and torsion of its appendix (hydatid of Morgagni), for, as McFadden (1939) remarks of the latter, the swelling and œdema are out of all proportion to the minuteness of the lesion.

Sudden pain accompanied by vomiting is more suggestive of torsion.

Absence of symptoms of cystitis and of urethritis should make one suspect torsion.

Palpability of Epididymis.—In cases of acute epididymitis it is nearly always possible to distinguish the enlarged epididymis from the body of the testicle. In cases of torsion it is usually impossible to palpate the two separately.

Redness, swelling, and œdema, which are always present in torsion, are also seen in some cases of acute epididymitis, and on local signs alone the two can in fact be indistinguishable. If these signs are found in a boy about the age of puberty or younger, torsion is almost certainly the correct diagnosis. If they are seen in an adult, acute epididymitis is more likely to be the cause of the symptoms. If, however, there is a complete absence of signs and symptoms suggesting urinary or prostatic infection, torsion has probably taken place. This is the more likely if there is a history of previous attacks of severe pain and swelling lasting only an hour or so.

PROGNOSIS

Spontaneous untwisting often occurs, but unfortunately further attacks of torsion are only too common. If untwisting does not take place, the testicle will undoubtedly become gangrenous. How soon this will happen is unknown: forty-eight hours is the critical time usually mentioned, but no doubt it depends on the number of turns in the twist. If gangrene develops, the testicle will gradually shrink to a small painless fibrous knob no larger than a small marble. I have seen this in 2 cases in boys where reference to their notes showed that they had been previously treated for epididymitis. This process is usually called atrophy, but, as Roche (1928) stated, atrophy is a degenerative process in a living structure, and this is conversion of extravasated blood and the remains of the testicle into fibrous tissue.

If bilateral torsion takes place and gangrene follows on each side, the patient will manifestly be sterile. Whether he loses his libido or not does not seem to be known.

TREATMENT

The early case should always be operated on. If immediate surgery is not available, an attempt should be made to untwist the torsion. Nash (1893) successfully did this by twisting the right testicle to the right after turning it to the patient's left had aggravated the pain. Even if this manœuvre succeeds, the patient should be advised to have a subsequent operation to fix the testicle.

The testicle can be exposed through a scrotal incision and the tunica vaginalis opened. Roche (1928) recommended that the parietal layer of the tunica vaginalis should be preserved, but that one should reproduce the normal sessile type of testicle by incising the posterior layer and suturing the cut edges to the lateral margins of the testicle, so as to reproduce the "bare area." In cases 2, 8, and 10, where the testicle was obviously viable, I excised the parietal layer of the tunica vaginalis and sutured the tunica albuginea to the areolar tissue of the scrotum.

When at operation the testicle is gangrenous it is usually removed. This cuts short the patient's illness and relieves him of pain. I think, however, that if he has already had an orchidectomy on the other side, the torsion should be undone and the gangrenous testicle left in situ. The testicular remnant may preserve some of its interstitial cells and will at least have some psychological value.

The most difficult question to answer is whether or not one should explore the remaining (normal) testicle after a gangrenous one has been removed for torsion. This was done in Kennedy's (1948) first case, but no abnormality was found. If the remaining testicle has ever caused, or ever causes, symptoms suggesting torsion, it should be explored. The risk of operation must be negligible, and I think that, when one testicle has already been lost, that risk should be taken.

In the absence of such a history it is probably wiser to explain the position to the patient or his mother, and to emphasise the need for early medical advice at the first symptom.

Discussing this problem Kennedy (1948) cites the figures given by Riba and Schmidlapp (1946) as an argument against an exploratory operation—of 489 collected cases only 26 were bilateral.

SUMMARY

Twelve examples of torsion of the testicle or its appendix occurring in 11 patients are described.

Where the testis is fully descended, the condition is usually diagnosed as acute epididymo-orchitis with the result that gangrene often supervenes before operation is undertaken.

This differential diagnosis is discussed, and a plea is made for wider recognition of the true diagnosis.

Operation is advised in all cases if seen early enough.

I am greatly indebted to Mr. G. E. Neligan, Mr. Alan Perry, Professor Dix, Mr. Charles Donald, and Mr. G. C. Tresidder for permission to publish cases admitted under their care, and to Professor Dix for help in preparing this paper. Case 11 is published by permission of Dr. J. Harris, physician-superintendent of Claybury Mental Hospital, and Mr. E. C. B. Butler, of the London Hospital.

"In the middle of the nineteenth century the whole orientation of Surgery was shifted by the work of Simpson on anæsthetics and Lister on the control of infection. Operations became more common, and surgeons, inspired by the possibilities of this new field, became technicians, so that surgical technique in the modern sense was born. Advances in Operative Surgery were made rapidly and no organ was exempt from the encroachments of the surgeon's knife. The surgeon moved his home to the operating theatre and the ward became his week-end cottage.... What of the future? Slowly but surely there is a drift back from the theatre to the ward. Surgeons are coming to realise that, in their 'gold rush' from the first field to the second, much had been left behind that was uncultivated. In nine cases out of ten one surgeon of experience will perform the operation as well as another and, if our results are to improve, it will come once more from a study of the processes of healing and repair. We appreciate that when the patient leaves the theatre our job is but half done and that the convalescence, the subsequent health, or even the chances of survival may be prejudiced by the kind of after-treatment which he will be given."—H. From the Department of Hæmatology, Manchester Royal Infirmary and St. Mary's Hospitals, Manchester

MEGALOBLASTIC anæmia of pregnancy (the so-called pernicious anæmia of pregnancy) is usually held to be rare. Davidson (1951) saw 42 cases at Edinburgh between 1940 and 1951; Thompson and Ungley (1951) at Newcastle had records of 46 cases seen in 17 years; and a recent estimate from New Orleans (Lund 1951) states that 1 case of megaloblastic anæmia occurs to every 100 of iron-deficiency anæmia.

In most of the published cases the patients had severe anæmia when first diagnosed, and the disease was more often first discovered in the puerperium than before labour; for instance, only 8 of Thompson and Ungley's 46 patients were diagnosed before labour. In our opinion, now that antenatal supervision is so much more common, and now that better diagnostic methods are available, many more patients could be diagnosed during pregnancy, and some undoubtedly are disguised as "refractory anæmias" in pregnancy that clear up after labour. The early diagnosis of megaloblastic anæmia of pregnancy is of much practical importance for the patient, since we have, in folic acid, a means of treating these patients effectively.

TREATMENT WITH FOLIC ACID

Soon after folic acid was discovered to be effective in the megaloblastic anæmia of sprue and in addisonian pernicious anæmia, it was applied to megaloblastic anæmia of pregnancy and good results were reported by Moore et al. (1945) and by Spies (1946). Subsequent results have confirmed these early reports: Davidson et al. (1948) reported 4 successfully treated cases; Thompson and Ungley (1951) had a poor response in only 1 out of 7 patients treated. When vitamin B_{12} was introduced it was soon found to have no effect on megaloblastic anæmia of pregnancy as it occurs in temperate climates; the original report by Day et al. (1949) has been confirmed by others since. Folic acid therefore remains the treatment of choice for the megaloblastic anæmia of pregnancy, and its use in properly diagnosed cases can at least ensure that the patient is in reasonable condition to face her labour.

We describe here 6 cases, 5 of which were found within a period of six months when a special effort was made to find them; 4 patients were diagnosed during pregnancy. The patients were all seen in the antenatal clinic or in the wards at St. Mary's Hospitals, Manchester, and all have been successfully treated with folic acid.

CASE-RECORDS

Case 1.—This patient, aged 25, was 24 weeks pregnant in her second pregnancy when first seen at the antenatal clinic in April, 1947. There was no history of anæmia in the family or during her previous confinement; there had been occasional attacks of diarrhœa during this pregnancy, lasting 2–3 days at a time. On July 12, 1947, she appeared pale, listless, and ill, and she was admitted to the ward for investigation of severe anæmia. A blood-count showed Hb 5·6 g. per 100 ml., red cells 1,900,000 per c.mm., colour-index 1·0, and white cells 2600 per c.mm. She had complained of painful ulcers in her mouth for several days; these were superficial symmetrical ulcers on the tongue, pharynx, epiglottis, and nasal septum, 0·5–1·0 cm. in diameter, with yellow sloughing bases and raised reddened margins. The Wassermann reaction was negative. There were no abnormal neurological signs. Sternal-marrow puncture revealed a predominantly megaloblastic marrow. Fractional gastric analysis showed a normal acid stomach content.

Treatment with folic acid 20 mg. daily by mouth was started. This was followed by a reticulocyte peak of 31% on July 20, and by July 24 a blood-count showed Hb 6·4 g. per 100 ml. and red cells 2,580,000 per c.mm. A sternal-marrow puncture was repeated, and this showed very few megaloblasts remaining.

Normal delivery of a living full-term child took place on Aug. 12. A blood-count on Aug. 21 showed Hb 10·4 g. per 100 ml., red cells 3,600,000 per c.mm., and colour-index 0·97.

Diet.—Careful inquiry revealed that the patient's diet had been full and adequate for pregnancy, and she had not been troubled by vomiting. After leaving hospital the patient was given desiccated stomach powder for two months. Thereafter she had no treatment. Seen on Jan. 4, 1952, she was in excellent health, with Hb 11·7 g. per 100 ml. and red cells 4,160,000 per c.mm.

Case 2.—This patient, aged 27, had had three previous normal confinements without anæmia. A month before term in her fourth pregnancy she was very pale, with a tinge of icterus, and a blood-count showed Hb 5·9 g. per 100 ml., red cells 3,581,000 per c.mm., colour-index 0·65, and white cells 9000 per c.mm. Her tongue, mouth, and throat had felt sore, and she had difficulty in swallowing. A course of intravenous iron injections was started, but the amount of hæmoglobin and the red-cell count remained stationary. A sternal-marrow puncture showed well-marked megaloblastic hyperplasia. A further blood-count showed Hb 6·3 g. per 100 ml., red cells 1,980,000 per c.mm., colour-index 1·13, and white cells 5000 per c.mm. A test-meal was abandoned because the patient could not retain the Ryle's tube.

Treatment was begun with folic acid 100 mg. in a saline intravenous drip, followed by 20 mg. by mouth daily. She began to feel much better.

Normal delivery took place on Nov. 24, 1951. A blood-count on Dec. 3 showed Hb 13 g. per 100 ml., red cells 3,840,000 per c.mm., colour-index 1·13, and white cells 6100 per c.mm.

Diet.—There had been a serious deficiency of meat and green vegetables, and the patient admitted that she did not spend much on food. Her appetite had been poor during pregnancy, partly owing to nausea and occasional vomiting.

Follow-up.—She was last seen on April 8, 1952, when a blood-count showed Hb 11·7 g. per 100 ml., red cells 4,120,000 per c.mm., colour-index 0·96, and white cells 6250 per c.mm. She had had no folic acid for four months.

Case 3.—This patient was a primigravida, aged 24, whose anæmia became apparent in the puerperium. She was delivered of twins on April 5, 1951, when she had a postpartum hæmorrhage of about 20 oz. She was transfused at the time with 2 pints of blood. Tachycardia and slight pyrexia followed, and she appeared still very anæmic.

On examination the spleen was just felt. A blood-count showed Hb 6·8 g. per 100 ml., red cells 2,180,000 per c.mm., and colour-index 1·09. A sternal puncture showed the red-cell series to be extremely active, with a very high proportion of pro-erythroblasts; some definite transitional megaloblasts were present. A fractional test-meal revealed a normal acid secretion.

Folic-acid therapy was started with 30 mg. intramuscularly for the first three days, and continued with 20 mg. daily by mouth thereafter. Subsequent blood-counts were:

May 7	Hb	11·5	g./100 ml.,	red cells	3,920,000/c.mm.,	c.i.	1·00
June 18	,,	13·0	,,	,,	4,420,000	,,	1·00
Nov. 5	,,	13·9	,,	,,	4,910,000	,,	0·96

Folic-acid therapy was discontinued on June 18, 1951. Inquiry revealed no personal or family history of anæmia.

The patient's diet had been notably deficient in meat and green vegetables; the bulk consisted of potatoes or other cooked root-vegetables, supplemented by cake, biscuits, or bread.

Case 4.—Normal full-term delivery took place on Oct. 11, 1951, in this 2-para aged 37. Because of extreme pallor 18 days after delivery a blood-count was done, which showed Hb 8·1 g. per 100 ml., red cells 2,590,000 per c.mm., colour-index 1·1, and white cells 9400 per c.mm. For 3 weeks before delivery she had felt rather weak and had noticed that her tongue was sore and "raw." Sternal-marrow puncture showed a hyperplastic megaloblastic picture. Fractional gastric analysis revealed achlorhydria.

Folic acid 20 mg. daily orally was given with the following results:

Nov. 9	Hb	10·1 g./100 ml.,	red cells	2,490,000/c.mm.,	c.i.	1·30
,, 16	,,	11·5 ,,	,,	3,000,000 ,,	,,	1·26
Dec. 7	,,	13·9 ,,	,,	3,670,000 ,,	,,	1·30
Jan. 25	,,	14·1 ,,	,,	4,650,000 ,,	,,	1·03

Inquiry revealed, once more, no history of anæmia or of dietary deficiency. Folic-acid treatment was stopped in February, 1952, and so far the patient has remained well.

Case 5.—A 2-para, aged 26, expected confinement on Dec. 2, 1951. On Nov. 19 she complained of sore tongue, gradual loss of weight, and dyspnœa on exertion.

On examination she was not very pale, but her tongue was red, smooth, and swollen. A blood-count showed Hb 11·6 g. per 100 ml., red cells 3,100,000 per c.mm., colour-index 1·22, white cells 5200 per c.mm. Sternal-marrow puncture showed a megaloblastic hyperplasia with many hæmocytoblasts and pro-erythroblasts. Fractional gastric analysis showed a normal acid content.

Folic-acid therapy was started with 30 mg. intramuscularly, and continued with 20 mg. by mouth daily thereafter. By Nov. 26, 1951, the tongue was no longer sore and red, though it was still smooth and glazed. A blood-count, however, showed no change.

Normal delivery took place on Nov. 29, and a blood-count on Jan. 17, 1952, showed Hb 14·2 g. per 100 ml., red cells 4,540,000 per c.mm., colour-index 1·06, and white cells 5450 per c.mm.

Diet.—There had been no previous history of anæmia before or during the previous pregnancies, and for 6–8 weeks before the start of folic-acid therapy the soreness of her tongue had prevented her from eating almost anything. A week after the start of treatment she could eat again. The diet itself revealed no gross deficiencies.

Case 6.—This patient, aged 29, was about 5 months pregnant in her seventh pregnancy when first seen at the antenatal clinic. There was a history of anæmia in her fifth pregnancy, treated with iron and "liver injections." There was some pallor evident at her first attendance, and a blood-count showed Hb 7·4 g. per 100 ml., red cells 3,912,500 per c.mm., colour-index 0·65, and white cells 15,600 per c.mm. She was given large doses of iron by mouth, under the care of her own doctor, but at the 34th week of pregnancy her hæmoglobin was still only 8·1 g. per 100 ml.; so she was admitted to the ward and given a transfusion of 2 pints of packed red cells; this increased the hæmoglobin to 10·2 g. per 100 ml. Two weeks later a blood-count showed Hb 8·6 g. per 100 ml., red cells 3,650,000 per c.mm., colour-index 0·8, and white cells 10,500 per c.mm. A sternal-marrow puncture showed well-marked hyperplasia with some transitional megaloblasts and large metamyelocytes. A mixed iron-deficiency and megaloblastic anæmia of pregnancy was diagnosed.

Treatment was begun with folic acid 20 mg. by mouth daily, together with oral iron as before. Fractional gastric analysis showed a normal stomach acid content, and on Nov. 26, 1951, a blood-count showed Hb 9 g. per 100 ml., red cells 3,900,000 per c.mm., colour-index 0·78, and white cells 7200 per c.mm.

Normal delivery took place on Dec. 3, but was complicated by a postpartum hæmorrhage of about 40 oz. On the 3rd puerperal day the Hb was only 8·7 g. per 100 ml., and on the 5th day the patient was given 1 pint of packed red cells, after which the hæmoglobin rose to 10·5 g. per 100 ml. On the 18th day after delivery she was discharged home, and continued with folic acid and iron by mouth.

Follow-up.—She was last seen on Jan. 7, 1952, when she had a much better colour and a blood-count showed Hb 12·5 g. per 100 ml., red cells 4,330,000 per c.mm., colour-index 0·98, and white cells 9450 per c.mm.

Diet.—Her diet appeared to have been quite adequate, and vomiting had not seriously interfered with this. She admitted to having had a sore tongue shortly before admission at the 34th week of pregnancy, without ulceration.

DISCUSSION

The average age of our patients was 29, and only 1 had had anæmia before, of unknown type, in pregnancy. 5 patients developed sore tongue with or without buccal ulcers; 5 had dyspnœa on exertion; 1 complained of dysphagia; vomiting in late pregnancy was slight in 2; and 2 had short bouts of diarrhœa. None showed any abnormality in the central nervous system.

Diagnosis in all our cases depended on examination of the sternal marrow. This procedure is essential in severe anæmia of pregnancy or of the puerperium, particularly in the patient who begins with an iron-deficiency anæmia but responds disappointingly even when intravenous iron is given. The bone-marrow picture is sometimes classically megaloblastic, but more often there are many pro-erythroblasts and normoblasts, and relatively few megaloblasts. In the early cases the picture shows "transitional" erythroblasts and typical large metamyelocytes (see Israëls 1951). Fractional gastric analysis is also important; 4 of our patients had free hydrochloric acid. The achlorhydric patients should be followed for at least twelve months after treatment has been stopped, in case they turn out to have addisonian pernicious anæmia; in practice this development is unusual, but case 4 in our series is a possible example. Ideally the achlorhydric patient should be given a course of vitamin B_{12} first, to see if she responds; but only too often time is too short, and the hæmoglobin level too low, to allow this experiment.

All our patients were treated with folic acid. This is usually given orally in a dose of 20 mg. daily; but, if time is short, it can be given intramuscularly (30 mg. daily for three days) or intravenously (100 mg. diluted in 250 ml. of saline solution given through the usual drip apparatus). Maintenance with a daily oral dose of 20 mg. of folic acid should be continued into the puerperium until the blood-count has been normal for a month; folic acid can then be withheld, but the blood-count should be checked again later.

Some of the patients treated with folic acid who have not had previous iron treatment later develop an iron-deficiency type of anæmia that will need oral iron as well as folic acid. If the woman is first seen very late in the pregnancy, or has severe blood-loss at labour, blood-transfusion may be needed to tide over the immediate emergency; but, of course, treatment with folic acid, and iron if needed, should be begun as soon as possible.

The prognosis, especially if the patient is seen and the condition diagnosed and treated well before labour, is excellent for both mother and child. For this reason we emphasise the importance of being on the alert for the early case of megaloblastic anæmia of pregnancy; and it should be remembered that the peripheral blood picture may be atypical, especially if the common iron-deficiency anæmia is present as well. Bone-marrow biopsy is essential to make the diagnosis certain.

SUMMARY

Six cases of megaloblastic anæmia of pregnancy which responded satisfactorily to folic-acid treatment are described.

The paramount importance of bone-marrow biopsy for correct diagnosis is emphasised.

The possibility that megaloblastic anæmia is present should always be considered when an anæmic pregnant patient does not respond as expected to iron.

Details of folic-acid treatment are given.

We are indebted to Dr. R. Newton and other members of the consultant staff at St. Mary's Hospitals, Manchester, for facilities for investigating patients under their care.

THE left auricular pressure has been directly recorded at operation in 37 patients, before and after valvulotomy, and in 14 patients with normal hearts during thoracotomy for various pulmonary diseases. The objects were to determine:

1. The form of the normal left auricular pressure pulse.
2. The form of the left auricular pressure pulse in mitral valve disease.
3. The changes in left auricular pressure following mitral valvulotomy.

We hoped to detect gross mitral incompetence unrecognised clinically, so as to spare such patients a needless digital exploration of the valve with its risk of systemic embolism. This object was not fully attained.

METHODS

Pressures were recorded through fine needles (21–23 s.w.g.) attached to cardiac catheter tubing * with acrylic cement.† The tubing bore was 1 mm., its length 1 metre. An electromanometer (Sanborn) and direct writer were used to record the pressure and electrocardiogram (lead I) simultaneously at a paper speed of 25 mm. per second. Some pressures, however, were recorded at 50 mm. per second. The level of the left auricle was taken as zero. Each recording was calibrated with a mercury manometer.

In the patients with mitral stenosis the needle was inserted into the intact left auricle with the pericardium open. The post-valvulotomy tracings were taken after the auricle had been sewn up. In the control series the pericardium was not opened, the needle being passed into the auricle through a pulmonary vein. In 3 patients a right auricular tracing was recorded simultaneously with the left. For some of the records a fine stylus was used, and these tracings have been darkened for reproduction.

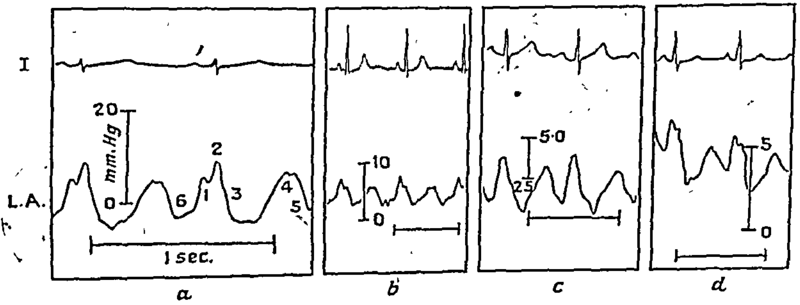

Fig. 1—Simultaneous lead I (E.C.G.) and left auricular pressure tracing in 4 patients with normal hearts. Time base = 1 sec. Pressures = mm. Hg.

The anæsthetic agents were thiopentone, curare, and a 50% oxygen/nitrous oxide mixture. Respiration was arrested during the recording of the pressures.

Mitral valvulotomy was performed digitally.

RESULTS

Left Auricular Pressure in the Normal Heart

The form of the left auricular pressure tracings were similar in the 14 patients. There were six main features, best illustrated by fig. 1*a*, which was recorded at a paper speed of 50 mm. per second:

(1) A wave, due to auricular systole, whose peak preceded the Q R S complex. Its amplitude, measured from the level at the end of diastole, varied in the 14 patients from 2 to 8 mm. Hg.

(2) A deflection beginning at the end of the Q R S complex—i.e., at the onset of ventricular systole. This was sometimes only just identified (fig. 1*b*) or absent (fig. 1*c*).

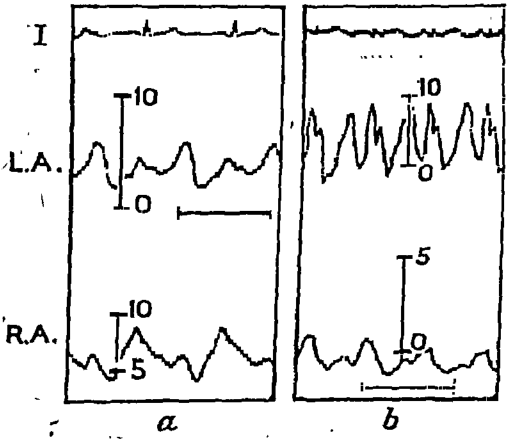

Fig. 2—Simultaneous lead I (E.C.G.) and left auricular and right auricular pressure tracings in 2 patients with normal hearts.

(3) A fall in pressure in early ventricular systole usually reaching to near the level at the end of diastole.

(4) A rise in pressure during late ventricular systole reaching a peak 0·04–0·12 sec. after the end of the T wave and measuring 1–9 mm. Hg above the pressure at the end of diastole.

(5) A steep fall in pressure at the opening of the mitral valve.

(6) A slight rise preceding auricular systole.

The left and right auricular pressure pulses recorded simultaneously (fig. 2*a* and *b*) were similar in form, although the amplitude of the late systolic wave in the left auricle was greater than in the right. The peaks of these waves were synchronous.

Left Auricular Pressure Pulse in Mitral Stenosis

No patient with clinical or operative evidence of mitral incompetence has been included.

With sinus rhythm.—This group comprised 19 patients. The form of these tracings, with some exceptions, resembled the normal (fig. 3*a*, *b*, and *c*), although the pressures were higher.

The pressure rise with auricular systole was surprisingly small, ranging from 1 mm. Hg (fig. 3*d*.) to 11 mm. Hg

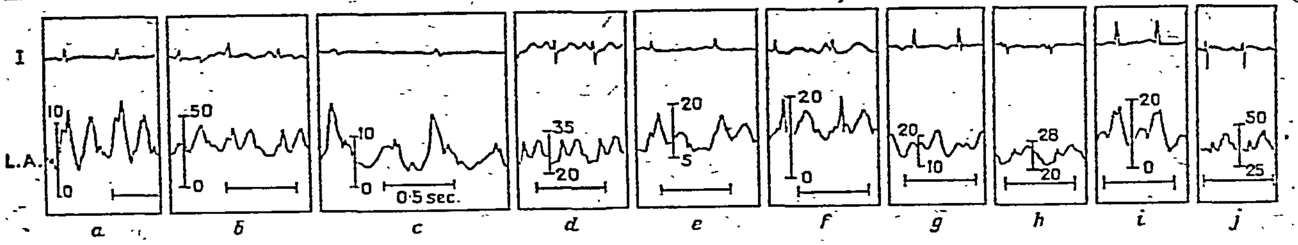

Fig. 3—Simultaneous lead I (E.C.G.) and left auricular pressure tracings in patients with mitral stenosis and sinus rhythm.

(fig. 3c) above the level at the end of diastole. It tended to be greatest when this level was low.

The pressure rise at the onset of ventricular contraction was usually greater than in the normal and began close to the peak of the auricular systolic wave (fig. 3e). Vibrations due probably to the first heart sound were sometimes also recorded at this time (fig. 3f).

The fall of pressure in early ventricular systole was as great as the normal in some patients (fig. 3a, b, c, f, and i) but slight or almost absent in 4 others—e.g., fig. 3g and h.

The pressure rise in late ventricular systole varied from 3 mm. Hg (fig. 3i) to 19 mm. Hg (fig. 3b) above the end diastolic level. The peak was closer to the end of the T wave (0·0–0·06 sec.) than in the normal.

With auricular fibrillation.—There were 18 patients in this group. The pressure in these patients rose sharply at the onset of ventricular contraction (figs. 4a–e and 5) and remained raised throughout. There was little or no drop in early systole except after a long preceding diastole (fig. 6a). In some tracings there was a considerable further rise in late systole—e.g., fig. 4e.

The pressure rise during ventricular systole tended to be greater when the end-diastolic pressure was high. Thus it was greater after a short preceding diastole than after a long one (fig. 6a) and greatly increased by tachycardia (fig. 6b).

The late systolic pressure peaks measured 3–16 mm. Hg above the preceding end-diastolic levels.

Left Auricular Pressure Pulse with Mitral Incompetence

Significant mitral incompetence was judged to be present at operation in 5 patients. Clinically an apical systolic murmur and considerable left auricular enlargement were also present. In 3 of these patients, with sinus rhythm, strong regurgitant jets were felt. The left auricular tracings (figs. 7a and b and 8) resembled those in patients with no evidence of mitral incompetence (compare with fig. 3j, f, and h respectively).

The auricular pressure rose sharply at the onset of ventricular contraction but then dropped in 2 patients to the end-diastolic level. The subsequent rise in late systole, measured from this level, was 25 mm. Hg in 1 patient (fig. 7a)—i.e., greater than the range seen in mitral stenosis alone—but only 8 mm. Hg in the other 2.

In the remaining 2 patients, who had auricular fibrillation, considerable mitral incompetence was considered to be present although no jet was felt. In each the orifice of the valve was about $1^1/_2$ times the diameter of the distal phalanx of the surgeon's index finger. The rigid calcified margins were felt to gape during ventricular contraction; no jet was felt, presumably because the mitral opening was relatively large. The left auricular tracings in these patients (fig. 7c and d) were similar to those obtained in mitral stenosis and auricular fibrillation. The pressure rise measured from the level at the end of the preceding diastole to the peak in late systole was 12 and 6 mm. Hg.

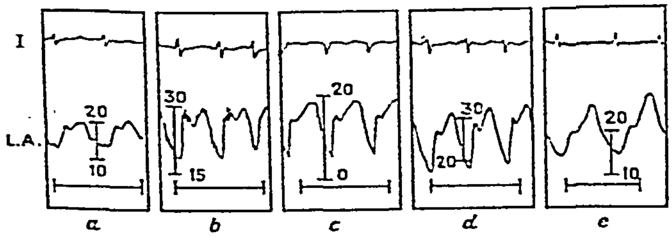

Fig. 4—Simultaneous lead I (E.C.G.) and left auricular pressure tracings in patients with mitral stenosis and auricular fibrillation.

Changes in Left Auricular Pressure Pulse After Valvulotomy

The changes in left auricular mean pressure after valvulotomy and the correlation between this and the clinical response will be published separately.

There were few significant changes in the form of the left auricular pressure pulse after operation, even in 3 patients in whom some mitral incompetence was produced. This was shown by a strong regurgitant jet and the development of a loud systolic murmur in the mitral area. In these patients, although the end-diastolic pressures in the auricle were lower after operation (fig. 9), the degree of pressure rise from the level at the end of diastole to the peak in late systole remained approximately the same, measuring 15, 8, and 7 mm. Hg compared with 14, 10, and 8 mm. Hg before operation.

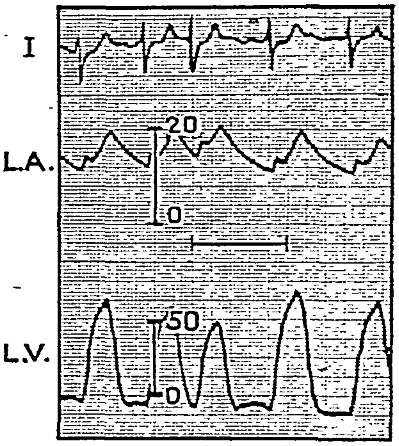

Fig. 5—Simultaneous lead I (E.C.G.) and left auricular and left ventricular pressure tracings in a patient with mitral stenosis and auricular fibrillation.

DISCUSSION

Hitherto only one left auricular pressure tracing in a normal human heart has been published (Munnell and Lam 1951), and this seems overdamped. However, tracings from the left auricle obtained by venous catheterisation in patients with atrial septal defects have been published by Cournand et al. (1947), Lagerlöf and Werkö (1949), and Calazel et al. (1951). In general the form of these curves is similar to our own.

The greater amplitude of the late systolic wave in the left auricle compared with the right has been shown to exist also in dogs by Opdyke et al. (1948). They attribute the difference to a lesser capacity and elasticity of the left auricle and pulmonary veins compared with the right auricle and systemic veins.

In the patients with mitral stenosis the pressure rise with auricular systole tended to be

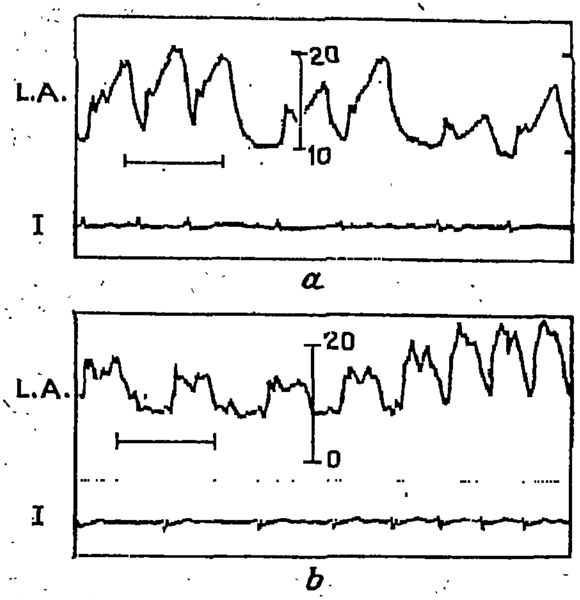

Fig. 6—Simultaneous left auricular pressure tracing and lead I (E.C.G.) in 2 patients with mitral stenosis and auricular fibrillation.

small, especially when the stenosis was severe, and the pressure at the end of diastole high. This pattern of response is familiar in relation to over-distension of the ventricular chambers (Wiggers 1952). The comparative weakness of auricular contraction may also be due to involvement of its myocardium in the rheumatic process, for Aschoff nodules were found in 30% of the auricular appendages amputated at operation (Pinniger 1952).

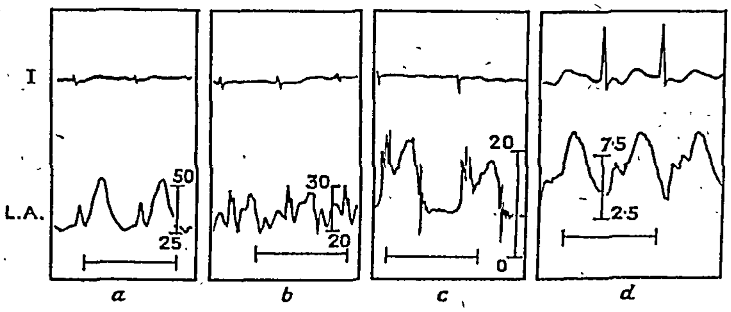

Fig. 7—Simultaneous lead I (E.C.G.) and left auricular tracing in 4 patients with mitral incompetence: *a*, *b*, sinus rhythm; *c*, *d*, auricular fibrillation.

The factors involved in the pressure changes in the auricle during ventricular systole in patients with mitral disease are complex, and detailed discussion must await the production of further data.

The pressure rise in the auricle with the onset of ventricular contraction may be due to inward bulging of the floor of the auricle and of the mitral valves. This was sometimes felt by the surgeon and is supported by observations on the movements of mitral calcification at fluoroscopy (Froment et al. 1950, Wynn 1952).

The variations in amplitude of the late systolic wave in the auricle is noteworthy. The factors which determine this may include the inflow from the pulmonary veins, mitral reflux, movements of the floor of the auricle, and the capacity and elasticity of the left auricle and pulmonary veins. The part played by mitral incompetence was difficult to evaluate because of the error inherent in the diagnosis of mitral reflux by palpation. Moreover, patients in whom mitral incompetence was thought on clinical grounds to be the predominant lesion were not submitted to operation. In only 2 of the 5 patients in whom mitral incompetence was found at operation was there no significant stenosis.

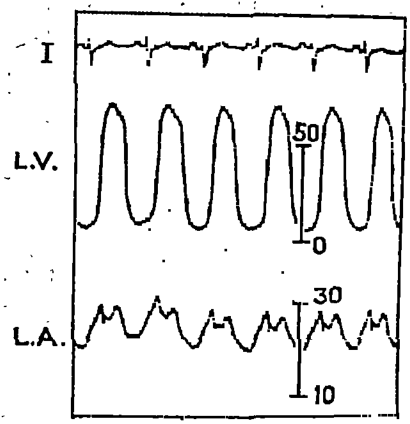

Fig. 8—Simultaneous lead I (E.C.G.) and left ventricular and left auricular pressure tracings in a patient with mitral stenosis and incompetence in sinus rhythm.

The experiments of Wiggers and Feil (1922) in dogs, which we have repeated and confirmed, suggest that mitral incompetence should increase the height of the late systolic wave. However, we have found at operation that the late systolic peak was as high in mitral stenosis as in 4 of the 5 patients with mitral incompetence and in the 3 patients in whom mitral incompetence was produced acutely by operation.

These observations are relevant to recent attempts to diagnose mitral incompetence from the prominence of the late systolic wave in "pulmonary capillary" tracings which are thought to reflect the pressure changes in the left auricle (Lagerhöf and Werkö 1949; Gorlin et al. 1952). These workers also consider that the absence of a fall in pressure in early ventricular systole in "pulmonary capillary" tracings is characteristic of mitral incompetence. However, in our left auricular tracings there was no pressure fall in early ventricular systole in 5 patients in sinus rhythm, of whom only 1 had evidence of mitral incompetence at operation. Moreover, this fall in pressure was slight or absent in all the patients with mitral stenosis and auricular fibrillation.

In the patients with auricular fibrillation the abrupt and sustained auricular pressure pulse with ventricular systole was striking. Its greater prominence when the end-diastolic pressure in the auricle was high, and the variations in its form and amplitude with the length of the preceding diastole (fig. 6*a*), underline the importance of the distension of the auricle at the onset of ventricular systole in determining the pressure changes within it. Thus with the decrease in distension at the end of a long diastole the sub-

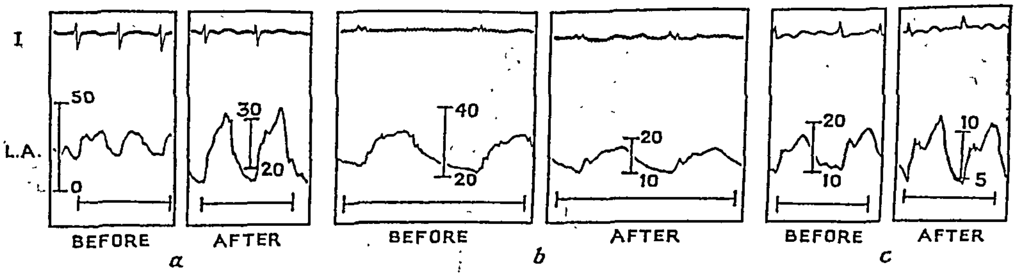

Fig. 9—Simultaneous lead I (E.C.G.) and left auricular pressure tracings before and after valvulotomy in 3 patients with mitral stenosis and auricular fibrillation who developed mitral incompetence after operation.

sequent rise with ventricular systole was smaller. If mitral reflex was the main factor causing this rise in pressure, this response would not be expected. The greater ventricular filling after a long diastole leads to a higher systolic pressure peak in the left ventricle (fig. 5) and hence a greater pressure differential between the left ventricle and left auricle. In these circumstances mitral reflux and the auricular pressure changes resultant from it should increase.

SUMMARY AND CONCLUSIONS

The left auricular pressure pulse has been studied at thoracotomy in patients without heart-disease and before and after mitral valvulotomy in patients with mitral valve disease.

In 14 normal persons the pressure rise with auricular systole was 2–8 mm. Hg, and the pressure rise in late ventricular systole 1–9 mm. Hg. The form of the pulse in the left auricle resembled that in the right, but the pressure rise in late systole was greater.

In mitral valve disease with sinus rhythm the form of the auricular pressure pulse usually resembled the normal, though the pressures were higher. The pressure rise with auricular systole above the level at the end of diastole was 1–11 mm. Hg and in late ventricular systole 3–19 mm. Hg.

In auricular fibrillation the auricular pressure rose abruptly with the onset of ventricular contraction. There was usually little fall in pressure in early systole and a variable further rise in late systole, but this was modified by the length of the preceding diastole.

The pressure peak in late systole was 2·5–16·0 mm. Hg above the previous end diastolic level.

In 8 patients with evidence of mitral incompetence, including 3 in whom this developed after valvulotomy, no significant difference in the form of the left auricular pressure pulse was found from those considered to have mitral stenosis alone. However, in 1 patient, in sinus rhythm, with preoperative mitral incompetence, the pressure rise in late systole was 25 mm. Hg.

In the presence of mitral stenosis, mitral regurgitation does not appear to produce any qualitative change in the form of the left auricular pressure tracing. Quantitative changes are difficult to assess because the major variable which determines them is the degree of distension of the auricle at the onset of ventricular contraction.

We are deeply grateful to Mr. N. R. Barrett and Mr. M. Meredith Brown for their patient coöperation in the operating-theatre. We should like to thank Dr. Evan Jones and Dr. A. C. Dornhorst for their helpful advice and criticism, Dr. James Sharkey for assistance in the early part of the investigation, Miss Z. Taylor for technical aid, and Mr. A. L. Wooding for reproduction of the tracings. The cost of the investigation was partly defrayed by a grant from the St. Thomas's Hospital Endowments Fund.

From the Medical Research Council's Blood Transfusion Research Unit, Postgraduate Medical School of London

UNTIL comparatively recently little stress has been laid upon qualitative differences between immune and naturally occurring forms of anti-A. Previously it was considered that any strong anti-A serum would hæmolyse A cells if complement were present. Apparent discrepancies between the iso-agglutinin content of a serum and its hæmolytic effect were thought to be due to failure to standardise the amount of complement in the test (Wiener 1943). Nevertheless, as early as 1941 Wiener called attention to the change in the thermal optimum of anti-A agglutinins following incompatible transfusions and suggested that this might be a valuable sign of the formation of "immune antibody." This implied that qualitative differences existed between immune and naturally occurring forms.

The next qualitative difference to be demonstrated was that revealed by performing titrations in a medium of serum. Boorman, Dodd, and Morgan (1945) observed that, when anti-A sera were tested in doubling dilutions against A cells, their reactivity might be enhanced by diluting with serum rather than with saline solution. This effect was not observed when testing naturally occurring anti-A and was only observed when testing sera from people who had recently received an A stimulus.

Meanwhile an "incomplete" or "blocking" form of Rh antibody had been described (Race 1944, Wiener 1944), and it had been shown that this form of antibody was more heat-stable than the ordinary agglutinin. Boorman and Dodd (1946) demonstrated a similar form of antibody in two immune anti-A sera. They showed that by heating the serum to 75°C for twenty minutes its power of agglutinating cells suspended in saline solution was abolished, but that it would now "block" the reaction between A cells and naturally occurring anti-A. Moreover, A cells which were exposed to the heated serum and washed were agglutinated by an anti-globulin serum.

Witebsky (1948) described some further characteristics of immune anti-A sera. He showed that, if certain anti-A sera were treated with AB substance so that they would no longer agglutinate A cells suspended in saline solution, they would nevertheless agglutinate the same cells suspended in serum. Treatment of the sera with an appropriate dose of A substance was described as "partial neutralisation." Witebsky also showed that the same immune sera, unlike control sera, would fix complement in the presence of soluble A substance.

Ervin and Young (1950) and Ervin et al. (1950) studied hæmolytic transfusion reactions caused by the transfusion of group-O blood to group-A people. They found that in every case the donor's serum displayed the "immune" characteristics described by Witebsky. They extended Witebsky's observations by showing that partially neutralised immune anti-A sera would sensitise A cells to an anti-globulin serum. They also found that the sera of 12 out of 100 random group-O donors displayed "immune" characteristics.

The present paper describes the incidence of these "immune" forms of anti-A in a sample of the English

---

[*] A short account of these findings was given to the International Congress of Clinical Pathology in July, 1951.

population. It also describes the development of these forms in people receiving various stimuli, and shows that injections of certain vaccines and animal sera often lead to the production of "immune" anti-A. Finally, attention is drawn to the probable clinical importance of these antibodies.

Methods

Titration in Saline Solution

Doubling dilutions of the test serum were made in saline solution in "agglutinin tubes" of 6 mm. diameter. The diluted serum in each tube was mixed with an equal volume of a 2% suspension of cells in saline solution (0·2 ml. of packed cells + 9·8 ml. saline). For anti-A titrations cells of subgroup A_1 were used. In some cases a direct dilution of 1/200 was made by adding 0·02 ml. serum to 4 ml. saline. One volume of this dilution was mixed with an equal volume of a 2% suspension of cells.

In all the cases the mixtures were examined for agglutination after two hours at room-temperature. The reciprocal of the highest dilution which produced clumps of 8–12 cells ("(+)" in the notation of Taylor et al. 1942) was recorded as the titre of the serum. The convention was adopted of ignoring the volume of cell suspension in calculating the final dilution of the serum.

Titration in Serum

The technique described for titrations in saline solution was followed, except that the test cells were suspended in group-AB serum and that AB serum was used instead of saline solution as the diluting medium.

Detection of Hæmolysins

Whenever possible, a fresh sample of serum was obtained for testing for hæmolysins. In these cases one volume of serum was mixed with a 5% suspension of cells in saline solution. After standing at 37°C for two hours the mixture was agitated and centrifuged, and the supernatant fluid was examined. The results were recorded as follows:

Complete hæmolysis	+ + +
50% hæmolysis ..	+ +
20% hæmolysis ..	+
Trace hæmolysis ..	tr.
No trace of pink colour	0

When the serum could not be tested on the day of taking, complement was added in the form of fresh human serum. For this purpose a single donor of group O was used whose serum contained weak anti-A and anti-B agglutinins and no anti-A or anti-B hæmolysin. Occasionally, fresh AB serum was used as a source of complement; and it was noted that if the AB serum was added to the anti-A serum before the addition of the test cells, hæmolysis might be inhibited, as originally observed by Moss (1910). This inhibition could be minimised by suspending the test cells in AB serum before adding them to the anti-A serum.

Indirect Anti-globulin Tests using "Partially-neutralised" Serum

Sera were tested as follows:

One volume of serum was added to each of three tubes. To tube 1 was added a half-volume of saliva from an A or B secretor; to tube 2 one volume of saliva; and to tube 3 two volumes of saliva. After half an hour at room-temperature one drop of a 50% suspension of test cells (A_1 or B) in saline solution was added to each tube. The mixtures were incubated at 37°C for two hours and examined for macroscopic agglutination. The unagglutinated mixtures were washed three times in saline solution, and the cells finally resuspended in 2 drops of saline solution. One drop of the suspension was mixed with one drop of anti-globulin serum on an opal tile, rocked gently over a source of light, and examined for the development of agglutination; a second drop of red-cell suspension was mixed with a drop of saline solution and examined similarly. The anti-globulin serum was used at the dilution which had previously been found to give the best reaction with Rh+ cells weakly sensitised with Rh antibody.

In exceptionally potent sera the agglutinin may not be neutralised by the addition of 2 volumes of saliva. It is not practicable to add relatively greater volumes of saliva, because the mixture then becomes so hypotonic that red cells are lysed. In such cases the agglutinin can conveniently be neutralised by the addition of purified group-specific substances (as prepared, for example, by Messrs. Sharp & Dohme, U.S.A.).

TABLE I—RELATION OF PREVIOUS HISTORY TO INCIDENCE OF α HÆMOLYSIN IN SERUM OF UNSELECTED GROUP-O DONORS

History	No. of donors	Hæmolysin present	Agglutination at dilution of 1/200
Injections during war service (1939–48)	27	10 (*37%*)	17 (*63%*)
Previous injection of anti-tetanus serum (only)	12	2 (*16%*)	5 (*42%*)
Previously pregnant	32	5 (*16%*)	17 (*53%*)
Remainder	54	5 (*9%*)	21 (*39%*)
Total	125	22 (*18%*)	60 (*48%*)

For the distribution of hæmolysins, $\chi^2 = 9{\cdot}71$ for 3 d.f.; $P < 0{\cdot}05$.

Choice of Group-A Donors

Donors of test cells were classified as A_1 or A_2 according to their reactions with an α_1 serum. Persons who reacted strongly with the α_1 serum were classed as A_1, and those who failed altogether to react were classed as A_2. Thus the use of "A intermediates" was avoided.

Clinical Material and Results

UNSELECTED GROUP-O DONORS

At two routine bleeding-sessions of the National Transfusion Service 125 consecutive group-O blood donors were questioned about past injections of various kinds, past transfusions, and past pregnancies. A sample of serum was obtained from each pilot tube for examination. From this survey several points of interest emerged.

Relation Between History of Prophylactic Injections and Characteristics of Anti-A

In table I the donors have been divided into four groups based on the answers given to various questions. Donors who had received injections during war service—presumably mostly T.A.B. vaccine and tetanus toxoid—had a significantly higher incidence of anti-A hæmolysin than others. They also appeared to have a higher incidence of high agglutinin titres, but this difference was not significant. Donors who gave no history of injections of vaccine or anti-tetanus serum ("remainder") had a significantly lower incidence of hæmolysin than those in the other groups.

The over-all incidence of anti-A hæmolysin in the 125 donors was 18%, defining a hæmolytic serum as one which gave a reaction of "+" or more; 48% of the donors had an agglutinin titre of 1 in 200 or more (the dilution of the serum being made in a single step).

Discrepancies Between Agglutinin Content and Immune Characteristics

Most of the sera with moderate or low agglutinin titres were non-hæmolytic; thus, among 72 sera with agglutinin titres below 200 all but 4 failed to hæmolyse A cells. However, sera with greater than average agglutinin titres were not necessarily hæmolytic; thus, of 53 sera

TABLE II—RELATION BETWEEN HÆMOLYTIC POWER AND AGGLUTINATING POWER OF ANTI-A IN BLOOD OF 125 GROUP-O DONORS SELECTED AT RANDOM

Agglutination* in direct dilution of 1/200	Total no. of subjects	Hæmolysis			
		None (0 or tr.)	Strong		
			+	+ +	+ + +
Nil	72	68	1	2	1
W	7	6	1	0	0
(+)	22	16	3	1	2
+	15	9	2	1	3
+ +	9	4	0	4	1
Total	125	103	7	8	7

*The degree of agglutination is recorded in the notation of Taylor et al. (1942).

with agglutinin titres of 200 or more only 18 hæmolysed A cells, and among the 9 sera with the highest agglutinin titres only 5 were hæmolytic (table II).

Sera containing potent agglutinins did not necessarily sensitise cells to an anti-globulin serum. Moreover, many sera containing agglutinins of less than average potency were capable of sensitising cells. In 19 cases (not among the 125 selected donors), with agglutinin titres of 8–128, 10 sensitised cells to an anti-globulin serum.

Most of the sera which would hæmolyse cells would also sensitise cells to an anti-globulin serum. Among the 125 donors there were 22 sera which were hæmolytic, and of these only 6 failed to give a clear-cut positive anti-globulin test.

Examples of discrepancies between the agglutinin content and the presence of immune characteristics are given in table III.

SUBJECTS RECEIVING INJECTIONS OF HORSE-SERUM

Blood was withdrawn from adults attending the casualty department of Hammersmith Hospital to receive a prophylactic injection of anti-tetanus serum. 12 persons reported again nine to thirteen days after the injection, and a second sample of blood was then withdrawn. Of these 12, 6 belonged to group O and 2 to group B; of these 8 only 1 had α hæmolysin before injection.

TABLE III—DISCREPANCIES BETWEEN PRESENCE OF POTENT ANTI-A AGGLUTININ AND "IMMUNE FORMS" OF ANTI-A

Group-O donors	Titre in saline solution	Indirect anti-globulin test	Hæmolysis
Case 98	64	+ + +	+ + +
Case 49	512	0	0
Case 26	64	(+)	+ +

After injection all 8 had α hæmolysin, though it was weak in 2 and only really strong (++ or +++) in 2 others. 7 out of 8 people showed a rise in anti-A agglutinin titre. 6 out of the 8 gave a stronger indirect anti-globulin test with A cells after injection. 3 of the responses are shown in table IV to illustrate: (1) a good specific response (Ba); (2) a poor response (We); and (3) response of both anti-A and anti-B (Co); anti-B hæmolysin also developed in one of the other 5 group-O subjects.

In the 4 group-A subjects receiving anti-tetanus serum no increases in anti-B agglutinin titre were observed. None of the 4 showed anti-B hæmolysin either before or after injection or gave a positive indirect anti-globulin test with B cells.

Tests of Anti-tetanus Serum in Vitro

The power of the anti-tetanus serum to inhibit anti-A and anti-B in vitro was tested. The serum inhibited anti-A to almost the same extent as saliva from an A secretor: one volume of a 1 in 32 dilution of the anti-tetanus serum added to an equal volume of a weak anti-A serum (titre 1 in 8) prevented the anti-A serum from agglutinating A cells. The effect on anti-B was much smaller: a 1 in 4 dilution of the anti-tetanus only very slightly reduced the titre of an anti-B serum serum.

TABLE IV—CHANGES IN ANTI-A IN 3 SUBJECTS (GROUP O) FOLLOWING AN INJECTION OF ANTI-TETANUS SERUM

Subject	—	Before anti-tetanus serum: Agglutinin titre: In saline	Before anti-tetanus serum: Agglutinin titre: In serum	Before anti-tetanus serum: Hæmolysis	Before anti-tetanus serum: Anti-globulin test	9–13 days later: Agglutinin titre: In saline	9–13 days later: Agglutinin titre: In serum	9–13 days later: Hæmolysis	9–13 days later: Anti-globulin test

TABLE V—ANTI-A RESPONSES IN 3 GROUP-O SUBJECTS RECEIVING T.A.B. VACCINE

Subject	Before injection: Hæmolysis	Before injection: Agglutinin titre (in saline solution)	Before injection: Anti-globulin test	18 days after injection: Hæmolysis	18 days after injection: Agglutinin titre (in saline solution)	18 days after injection: Anti-globulin test
La	tr.	256	+	+ +	256	+ +
Sc	0	256	0	+ +	4096	+
Fa	0	64	(+)	0	512	+ + +

The material used in the above tests was horse-serum which had been submitted to peptic digestion. Through the kindness of Dr. J. W. Trevan, F.R.S., director of the Wellcome Institute, it was possible to test untreated serum in parallel. It was found that untreated horse-serum agglutinated human red cells of all groups. However, after five absorptions with group-A red cells it would no longer agglutinate cells of that group, and thus its power to inhibit human anti-A serum could be tested; no inhibiting power was found.

SUBJECTS RECEIVING T.A.B. VACCINE

A sample of blood was withdrawn from 14 R.A.M.C. officers of group O who were about to receive their initial injections of T.A.B. (typhoid, paratyphoid A, paratyphoid B) vaccine; a further sample of blood was withdrawn eighteen days later.

4 of the 14 sera hæmolysed A cells before immunisation; 1 of these 4 showed a considerable increase in hæmolysin after immunisation. Of the 10 officers who had no hæmolysin at all initially, 6 developed a substantial amount after immunisation.

The results of the indirect anti-globulin test were not in close agreement. Some who developed strong hæmolysin gave only a moderately strong indirect anti-globulin test, and some who developed no hæmolysin developed a strongly positive anti-globulin test. 7 out of the 14 officers showed a significant rise in anti-A agglutinin titre (fourfold or more). On the whole, the development of hæmolysin was related to a rise in agglutinin titre, though again there were some discrepancies. Some examples are given in table V.

TABLE VI—RESPONSES OF BOTH ANTI-A AND ANTI-B IN 2 SUBJECTS AFTER INJECTION OF T.A.B. VACCINE

Subject	—	Before injection: Hæmolysin	Before injection: Agglutinin titre	After injection: Hæmolysin	After injection: Agglutinin titre
Wa	α	0	32	+ + +	1024
	β	0	8	+ + +	256
Yo	α	0	256	+ + +	2048
	β	0	128	+	1024

3 sera hæmolysed B cells before injection; 1 of these 3 showed an increased lytic power after injection. In 3 other cases the serum became lytic for B cells only after injection. In 7 of the 14 cases the anti-B agglutinin titre increased fourfold or more after the injection of T.A.B. vaccine.

Examples of cases in which there were good anti-A and anti-B responses in the same person are shown in table VI.

Tests of T.A.B. Vaccine in Vitro

The T.A.B. vaccine used throughout was a batch of alcoholised vaccine produced by the Army Vaccine Laboratory, Everleigh. The medium on which the organisms are grown is a tryptic digest of agar.

The vaccine was found to inhibit anti-A and anti-B *in vitro*, *but it also inhibited anti-M*, and it was concluded that the effect was non-specific. A sample of vaccine was centrifuged, and the supernatant fluid was reserved for testing. The deposit was then washed three times in saline solution. The supernatant fluid showed the same non-specific inhibiting effects as the whole vaccine, but the deposit was without effect.

Injection of Washed Deposit

1 group-B and 2 group-O persons were given two injections of the well-washed deposit from 0·5 ml. of the original vaccine; the injections were given at an interval of a week. Serum was withdrawn a week after the second injection and tested in parallel with a sample drawn before injection. The post-injection samples did not hæmolyse A cells, and showed no significant change in agglutinin titre; nor did they give a positive indirect anti-globulin test with A_1 cells.

SUBJECTS RECEIVING AB SUBSTANCE

4 male volunteers (2 group A and 2 group B) received injections of AB substance prepared by Messrs. Sharp & Dohme; the material is prepared from horse stomach and hog stomach. 0·2 ml. of the material, well diluted in saline solution, was injected intravenously. The group-B subjects received two injections at an interval of ten days; the group-A subjects received a single injection.

In the first group-B person the anti-A agglutinin titre in saline solution rose from 8 before injection to 256 ten days after the second injection; in serum the titre was 512; no hæmolysin developed. In the second group-B person the anti-A titre rose from 512 to 1024 in saline solution, and from 512 to 4096 in serum; the serum became hæmolytic for A cells after the second injection.

In the group-A subjects there were moderate increases in agglutinin titre with the development of a weak hæmolysin in one case.

SUBJECTS RECEIVING PURIFIED HUMAN A SUBSTANCE

2 male volunteers belonging to group O received two intramuscular injections, each of 1 mg. of purified human A substance prepared by Dr. W. T. J. Morgan from fluid from a pseudo-mucinous ovarian cyst. The injections were given at an interval of nineteen days in the first case and seven days in the second.

In both subjects there was a big increase in agglutinin titre (from 8 to 1024 and from 64 to 4096) and an α-hæmolysin developed, to a titre of 4 and 8 respectively. Both post-injection sera gave positive indirect anti-globulin tests with A_1 cells after partial neutralisation.

GROUP-O WOMEN RECENTLY DELIVERED OF GROUP-A INFANTS

Samples of serum were available from 8 group-O Rh-positive mothers, each of whom had given birth to at least one infant affected with hæmolytic disease of the newborn due to anti-A. In each case the mother's serum taken on the day of delivery hæmolysed group-A cells (complete lysis of a 5% suspension) and, after partial neutralisation, gave a positive indirect anti-globulin test with A cells. In 5 out of 8 cases the agglutinin titres in saline solution were well within the normal range; in the remaining 3 cases the titre was 1024–2048. These cases will be reported in detail elsewhere.

TABLE VII—DEMONSTRATION OF INCOMPLETE α

—	Composition of saliva-serum mixtures			A_1 cells		A_2 cells	
	Vols. of A saliva	Vols. of saline	Vols. of anti-A serum	Anti-globulin serum	Saline	Anti-globulin serum	Saline
i	8	0	4	+	0	0	0
ii	6	0	6	++	0	0	0
iii	4	2	6	++	0	tr.	0
iv	2	4	6	++	+	(+)	0
v	1	5	6	+++	++	++	0

Note that mixtures i and ii sensitise A_1 cells but not A_2 cells to the anti-globulin serum; the A_1 cells are not agglutinated in the sali [illegible] A_1 cells but not A_2 cells in s [illegible] mixture are agglutinated by

DEMONSTRATION OF INCOMPLETE α IN IMMUNE ANTI-A SERA

Witebsky (1948), describing his technique for demonstrating incomplete anti-A, stated that the antibody was essentially anti-A_1. This claim was based on the observation that, when the serum was treated with sufficient AB substance to abolish, or greatly diminish, the reaction with A_1 cells in saline solution, it would still react strongly with the same cells suspended in serum but would not react at all with A_2 cells.

We thought it might be possible to demonstrate an incomplete α, as opposed to an incomplete $α_1$, if an immune anti-A serum was "neutralised" only to the point where it would no longer react with A_2 cells suspended in saline solution. Under these conditions immune anti-A sera agglutinated A_2 cells suspended in serum and sensitised them to an anti-globulin serum (table VII).

Method.—The mixtures of A saliva and anti-A serum (table VII) were left for twenty minutes; then 6 drops of each mixture were added to 1 drop of a 50% suspension of A_1 cells in saline solution, and 6 drops were added to a similar suspension of A_2 cells. After two hours the red cells were washed and added to anti-globulin serum on an opal tile; a second drop of cell suspension was added to 1 drop of saline solution as a control. The degree of agglutination was recorded.

Discussion

INCIDENCE OF IMMUNE FORMS OF ANTI-A IN POPULATION

The present results show that group-O and group-B subjects respond variably to A stimuli. Some have a rise of iso-agglutinin titre only, whereas in others the serum develops hæmolytic properties with little rise in agglutinin content. The ability to sensitise A cells to an anti-globulin serum also develops to a variable extent. It is difficult to define the proportion of people in the population whose sera display "immune" characteristics, since sera may show one but not all of these characteristics. However, the properties may be considered singly.

The present finding that the sera of about 20% of group-O subjects hæmolyse A cells may be contrasted with Jonsson's (1936) finding that the sera of males contained iso-hæmolysin in only 3·5% of cases. On the other hand, it agrees fairly well with the original observation that about 25% of sera (of all groups) contain isohæmolysin (Moss 1910). The proportion of sera which hæmolyse test cells depends on (1) the technique of the test—for example, the strength of the cell suspension and the time for which the mixtures are incubated—and (2) the proportion of people in the population who have recently received an A stimulus—e.g., anti-tetanus serum. Again, the sera of women will be expected to contain iso-hæmolysins more often than those of men, owing to the stimulus of heterospecific pregnancies (Jonsson 1936).

Similar considerations apply to the ability of a serum to react with A cells after partial neutralisation with A substance. Ervin et al. (1950) found that 12 out of 100 random samples of group-O serum, after partial neutralisation, would agglutinate A_1 cells suspended in serum and give a positive indirect anti-globulin test with A_1 cells. The present findings show that these properties are influenced by a variety of stimuli, and thus the proportion of sera displaying such properties will be expected to vary widely.

STIMULATION BY HETEROSPECIFIC ANTIGENS

Davidsohn (1938) first observed that in people receiving injections of horse-serum, and particularly in those who developed serum-sickness, there might be a considerable increase in the anti-A and anti-B titres of the serum.

The anti-tetanus serum at present used in Britain is a peptic digest of horse-serum; since the pepsin is prepared from hog-stomach—a well-known source of A-like substance—it would be expected that the present anti-tetanus serum would be a more effective stimulus than untreated horse-serum.

The present observations show that most group-O people who receive an injection of the treated anti-tetanus serum can be expected to produce immune anti-A. In a case which has been reported elsewhere a serious hæmolytic transfusion reaction followed the transfusion of group-O blood to a group-A person, and it was shown that the cause of the potent anti-A in the donor's serum was almost certainly an injection of anti-tetanus serum received five weeks previously (Mollison 1951).

The ability of vaccines to stimulate anti-A may depend on the medium on which the bacteria are grown. Dausset and Vidal (1951) encountered some severe hæmolytic reactions in group-A people who had received group-O blood, and showed that in every case the group-O donor had recently received an injection of diphtheria toxoid which had been prepared from bacteria grown on a medium containing a digest of hog stomach. Moullec (1947) had previously shown that extract of hog stomach was the source of the A-like substance in the toxoid.

Stimulation of anti-A by T.A.B. vaccine has not been reported previously. Balgairies and Christiaens (1938) found no change in iso-agglutinin titre in 2 group-O persons and 1 group-B person after the injection of *vaccin anti-typho-paratyphique*. Nevertheless stimulation of anti-A by paratyphoid bacilli would not be surprising in view of the observation of Eisler (1931) that the injection of paratyphoid-B bacilli into rabbits produces a serum which specifically agglutinates human group-A red cells. To test the possibility that the injection of such bacilli can evoke the formation of immune anti-A in man, 3 people were injected with the well-washed deposit of T.A.B. vaccine. None showed any evidence of anti-A stimulation. Nevertheless further experience will be necessary before it can be concluded with certainty that paratyphoid bacilli do not stimulate anti-A in man.

The T.A.B. vaccine used in the present experiments was prepared from bacteria grown on a tryptic digest of agar. As mentioned, no clear evidence was obtained from inhibition tests of the presence of A-like substance in the medium. Nevertheless it remains probable that it is the medium which is responsible for stimulating anti-A when the vaccine is injected into man.

CLINICAL SIGNIFICANCE OF IMMUNE FORMS OF ANTI-A

Witebsky (1948), and Young and his co-workers (Ervin et al. 1950, Ervin and Young 1950) have drawn attention to the clinical significance of immune forms of anti-A. Witebsky described a case of hæmolytic disease of the newborn due to anti-A, and showed that the mother's serum contained powerful "immune" anti-A. Ervin and Young described hæmolytic reactions in group-A recipients transfused with blood whose plasma contained immune forms of anti-A. Observations briefly presented here show that immune forms of anti-A are regularly found in the blood of mothers of infants with hæmolytic disease of the newborn due to anti-A. Other (unpublished) observations support the contention that there is a close relationship between the immune characteristics of an anti-A serum and its ability to cause the destruction of A cells in vivo after transfusion.

The evidence suggests that it may be more valuable, from a clinical point of view, to know whether a serum has immune characteristics than to know whether it has a high agglutinin titre. Experience suggests that an anti-A serum which, diluted 1 in 4 in fresh serum, will not lyse an equal volume of a 5% suspension of A_1 cells after two hours' incubation at 37°C., will not cause appreciable destruction of red cells when transfused to a group-A recipient. Judged by this criterion more than 90% of group-O people are safe universal donors.

Since it is very troublesome to screen all group-O donors, it would be a wise precaution to refuse as donors all people who had received an injection of any vaccine or animal serum during the previous three months. Alternatively, bottles of blood obtained from such people might be marked to indicate that they should be given only to group-O recipients.

Summary

Among 125 group-O donors, taken at random, there were 22 (18%) whose sera hæmolysed A cells. Those donors who had received injections of bacterial vaccines during war service had a significantly higher incidence of α hæmolysin than the rest.

"Immune" forms of anti-A developed in the sera of most group-O people receiving one of the following stimuli: T.A.B. vaccine, anti-tetanus serum, injection of human A substance, and injection of animal AB-like substance. In the anti-tetanus serum the source of the A-like substance is in all probability the pepsin, derived from hog stomach, used for digesting the horse-serum. In the T.A.B. vaccine the source of A-like substance has not been identified but seems more likely to lie in the medium than in the bacteria.

Of the various "immune" characteristics of an anti-A serum, the ability to lyse A cells is the easiest to detect. It is suggested that the hæmolysin titre of a serum gives a good indication of its ability to destroy A cells in vivo.

We are very grateful to Dr. J. D. James, director of the North London Blood Supply Depot, for arranging for us to test and question a large number of blood donors; to Dr. Dorothy M. Parkin for the supply of blood samples from patients receiving anti-tetanus serum; to Brigadier A. Sachs, director of pathology, the War Office, for permitting us to obtain blood samples from Army personnel; to R.A.M.C. officers for volunteering to provide blood samples; and to Dr. I. D. P. Wootton for collecting the samples.

THE ASSESSMENT OF GROWTH IN DISEASE

THE USE OF WETZEL'S GRID ILLUSTRATED BY RHEUMATIC FEVER

H. A. W. Forbes
D.M. Oxfd, M.R.C.P.
PHYSICIAN, SOUTH DEVON AND EAST CORNWALL HOSPITAL, PLYMOUTH

When children arrive at hospital having lost flesh, it is difficult to assess their subsequent weight changes during illness. The commonly used comparison of a patient's serial weights with standard monthly increments according to age and sex, which may be made by deriving an equation from mean values obtained by observation of the appropriate groups of normal children, is fallacious (Bransby and Gelling 1946, Friend and Bransby 1947); for children grow in spurts, and their increments in height and weight are variable in magnitude and time relations, as well as from one child to another. One is concerned, too, with the return of an individual to his or her optimal weight and not to an average. What is required is a method of utilising the weight changes on recovery so that each patient provides his own standard of normality, and the point in the illness when return to normal growth is achieved should be indicated as early as possible. Use of an index which includes a factor for age is undesirable because this involves comparing an individual's growth with that of the sample of the universe on which the index is based—e.g., Tuxford index, and red graph.

Two methods meet the requirements set out above. One method is to take the final weight on discharge from hospital as representing the optimal weight and to use it retrospectively. At best this is presumptive and is no use to the clinician at the bedside; but it may be of help when weight changes are being studied in a series of cases.

The other method is to use the "grid for evaluating physical fitness" described by Wetzel (1941, 1944). This grid is in two parts. The first is independent of age, consisting of weight plotted against height. Across this is a ladder-like scale running diagonally from the origin to the top right-hand corner of the graph. Each rung of the ladder represents an arbitrary value which Wetzel called an "iso-developmental level." Knowledge of an individual's height and weight can thus be used to determine this value, which can then be plotted against age on the second part of the grid. The first part of the grid gives a graph depending only on the individual's own growth, whereas the second relates this to that of the group of children upon whom was based the calculation of the percentiles drawn on it. Wetzel reported that normal children developed in such a way that the graph of their weight plotted on the first chart follows a straight line parallel to one running from the origin towards the top right-hand corner of the graph. The course of the individual's graph remains along the channel which is appropriate to his or her physique.

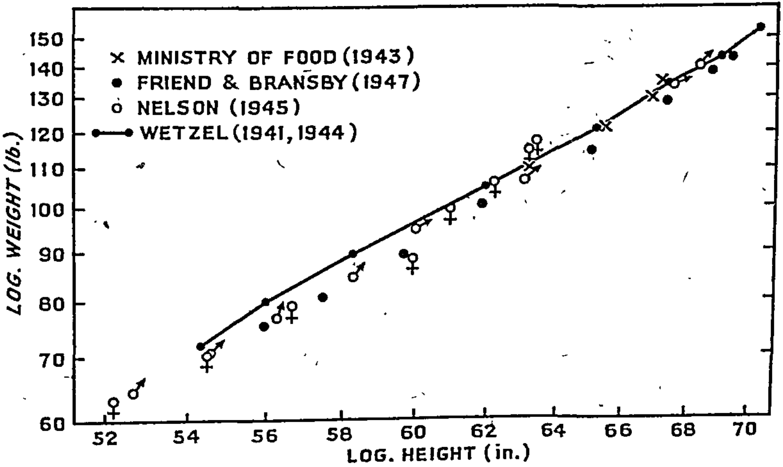

Fig. 1—Comparison of middle-channel values of Wetzel's grid with data from other sources on a double logarithmic scale.

To test whether Wetzel's observation that log-weight/log-height of growth was a straight line is applicable to British children, data from Friend and Bransby (1947), the Ministry of Food (1943), and Nelson (1945) were plotted against the values from the middle channel of Wetzel's grid. The mean height and mean weight for each group per year of age from the three sources mentioned above were used. The results are given in fig. 1 and show the good agreement obtained.

Until the age where the rate of height increase slackens and finally stops, the course of weight plotted against height on a double logarithmic scale is confirmed as being in a straight line. Girls' growth ceases to follow a straight line at about the age of 15, whereas that of boys follows it until the age of 18 or even more.

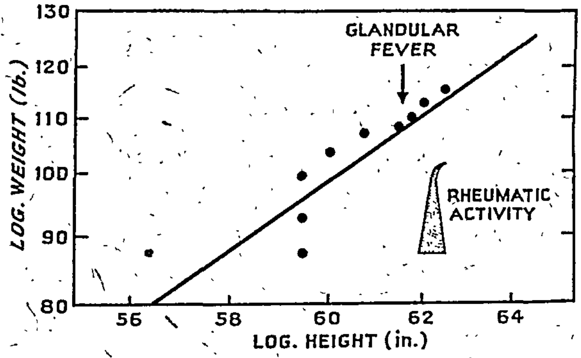

Fig. 2—Plotting points represent serial monthly observations from below upwards. Shaded wedge represents rheumatic activity great at first where base is wide and tapering off later. Line represents middle channel of Wetzel's grid.

The utility of Wetzel's principle was confirmed in a study of the criteria of rheumatic activity (Forbes 1952) when the period of observation was over four months. An example is given in fig. 2.

If reliable data are available from the period before the illness to indicate the patient's "physique channel," the graph could be used for a shorter period of observation. When the graph of the patient's growth ceased to be nearly vertical and turned obliquely into the channel appropriate to his physique, recovery from the illness was usually found by other tests and subsequent experience to be complete. Some children who had become over-fat in bed lost weight a little without apparent ill effect when physical activity was resumed.

Once the lost weight is regained the child may enter or remain in a period of "no growth." This is illustrated in fig. 3, where for four months there was no appreciable increase in growth without anything being untoward. Such a failure to gain weight would be interpreted by the standard monthly increments method as being abnormal.

It must, however, be pointed out, lest too much reliance be placed on the use of Wetzel's grid, that in rheumatic fever a steady gain in weight, not due to congestive heart-failure, is occasionally observed when rheumatic activity is continuing. In rheumatic fever many factors affect the patient's weight, among which may be the following:

(1) In the early stages the increase in body-fluids found to take place in rheumatic fever by Bradley (1938), Reid et al. (1950), and Cochran (1951), may mask the wasting, with the result that, when the patient recovers, reduction in both processes may lead to a lack of change in weight.

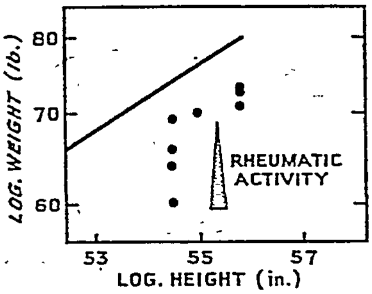

Fig. 3—Symbols as in fig. 2. Note four-month period of no growth though child was well.

(2) In spite of continuing rheumatic activity the placing of a rheumatic child at rest in bed may be sufficient to stop a loss of weight which would have occurred had the child remained ambulant.

(3) A child may be ill fed at home but, when placed on a good diet in hospital, may gain weight in spite of rheumatic activity.

SUMMARY

The problems of assessing weight changes in disease are discussed.

The underlying principle and advantages of Wetzel's "grid" as a solution are set out and illustrated by reference to rheumatic fever.

SURGICAL REGISTRAR

CHARING CROSS HOSPITAL

WHEN chronic ulcers of the leg were treated by covering them with a layer of amnion (Troensegaard-Hansen 1950, 1951), healing was sometimes delayed by bacterial infection. It is well known that *Pseudomonas æruginosa* may become established in chronic leg ulcers and is particularly difficult to eradicate.

PRELIMINARY TESTS

A 2% 'Phenoxetol' cream was used in the original treatment of ulcers with amnion, and acetic acid and sodium propionate have also been used in the past against pseudomonas infections. The inhibitory action of these compounds was tested as follows:

Cups 8 mm. in diameter were cut from nutrient agar plates. Three pseudomonas strains from chronic ulcers were spread on the plates, and the various preparations were placed in the cups. The results, using three different bases for the medium, are shown in the table. Inhibition depends largely on the ability of the drug to diffuse into the medium.

Trials of terramycin were not satisfactory.

A powder containing 1 part of terramycin in 200 parts of prepared starch (Boots K2S5) was applied to 6 chronic ulcers before covering them with amnion. The powder caked in the wound, and the antibiotic did not seem to penetrate the tissues; much pus formed and the membrane was displaced.

The use of chloramphenicol in propylene glycol was suggested by Dr. J. D. Gray, who had been using a solution containing 15 g. in 100 ml. in chronic otorrhœa (Lewis and Gray 1951). Propylene glycol has proved a satisfactory vehicle; it is non-toxic, miscible with water, and hygroscopic, and it can penetrate denuded surfaces.

Using the cup-plate technique ten organisms that were found resistant to 0·25% chloramphenicol in water were tested against 2·5% chloramphenicol in propylene glycol; there was a large zone of inhibition in each case. The organisms included *Ps. æruginosa*, two strains of *Staphylococcus aureus*, *Bacterium coli*, *Proteus vulgaris*, and two strains of streptococcus (non-hæmolytic and fæcal). Propylene glycol alone gave no inhibition.

RESULTS OF TREATMENT

The treatment previously described (Troensegaard-Hansen 1950) was used up to and including the scraping of the ulcer under general anæsthesia. A solution of 2·5% chloramphenicol in propylene glycol was then sprayed on the wound once daily. Most wounds were free from infection within 7 days. Amnion was then applied and covered with tulle gras, cotton-wool, and a light bandage. The patient stayed in bed, and dressings were left in place for six weeks if possible.

10 patients who had had ulceration of the legs for at least two years were treated in this way; 5 had associated varicose veins, and 4 had been unsuccessfully treated with phenoxetol and amnion. 7 of these ulcers healed in six weeks and 1 in three weeks; they have now remained healed for from six to eight months.

The 9th patient was a lady of 80; her ulcer healed in six weeks but recurred five months later.

The 10th patient had a chronic ulcer with eczema and swelling of the leg and foot. Local penicillin had previously produced a rash on the leg, but there was no other history of allergy or sensitivity, or of fungus infection. After two days' spraying with chloramphenicol in propylene glycol an urticarial rash appeared on the arms, the backs of hands, and the cheeks, but there was no local reaction. Treatment was stopped and saline dressings applied. On the eighth day she had an asthmatic attack; the acute phase subsided in twenty-four hours but her chest was not completely clear for a month. The ulcer remained clean, and amnion was applied after two weeks' treatment. The ulcer healed in six weeks, and the swelling and eczema of the leg also subsided, but a mild scaly eczema of the hands and forearms persisted.

One of these patients had a similar ulcer on the other leg which was treated with chloramphenicol in propylene glycol, but no amnion. At six weeks this ulcer was clean but unhealed; amnion was applied and the ulcer healed after a further six weeks.

INHIBITION OF *Pseudomonas æruginosa* BY PHENOXETOL, ACETIC ACID, AND SODIUM PROPIONATE IN DIFFERENT BASES

Reagent	Base		
	Ung. alcoh. lan.	Water	Ung. emulsif.
2% phenoxetol	−	+	+ + +
1% glacial acetic acid ..	−	+	+ +
10% sodium propionate ..	−	+	+ +
2% phenoxetol and 1% glacial acetic acid ..	−	+	+ + +
2% phenoxetol and 10% sodium propionate ..	−	+	+ + +

Equal effects were shown on three strains of *Ps. æruginosa*.
− = no inhibition.
+ = slight zone of inhibition at 8 hours, when growth was first obvious, but no inhibition at 20 hours.
+ + = slight zone persisting at 20 hours.
+ + + = moderate zone persisting at 20 hours.

A patient who was not treated with amnion had a band of ulceration, 6 in. wide, round the leg. Spraying with chloramphenicol in propylene glycol every other day has reduced it to 2½ × 1 in.

DISCUSSION

All the organisms isolated from these ulcers were sensitive to chloramphenicol in propylene glycol, as shown by a definite zone of inhibition in the cup test.

The possibility of local or generalised allergy can best be assessed by further trial of the method. Intradermal tests which we performed on our patient who had urticaria and asthma did not suggest that chloramphenicol was the sensitising agent. Pure propylene glycol produced a marked weal, but no surrounding erythema. A healthy adult control reacted similarly to the same amount intradermally. The weal was probably the result of absorption by the hygroscopic propylene glycol. In the 10th case it may be that the infection was overcome so rapidly that there was a sudden release of bacterial products. The patient may have been sensitive to the bacterial protein or to something else produced by the action of the antibiotic. If cultures were kept of organisms isolated from an ulcer, it would be possible to check this hypothesis by injecting a killed bacterial suspension, should an allergic reaction occur.

Despite the one reaction in this small series, chloramphenicol in propylene glycol seems to be a very useful adjunct to treatment with amnion.

We are grateful to Dr. J. Stanley White and Dr. Robert Hodgkinson of the department of clinical investigation of Messrs. Parke, Davis for supplies of chloramphenicol in propylene glycol.

SECRETION OF A SALT-RETAINING HORMONE BY THE MAMMALIAN ADRENAL CORTEX

In recent years the division of adrenal cortical steroid hormones into glucocorticoids and "mineralocorticoids" (Selye 1950) has been seriously questioned by some authors (Verzar 1952), and Conn, Louis, and Fajans (1951) have gone so far as to suggest that all the actions of adrenocorticotropic hormone (A.C.T.H.) in humans could be accounted for if the human adrenal be supposed to secrete 17-hydroxycorticosterone (Compound F) alone. Thus the three most active known glucocorticoids, cortisone, Compound F, and Compound B, all produce sodium retention in man (Sprague et al. 1950, Conn, Fajans et al. 1951, Conn, Louis, and Fajans 1951), and cortisone does so in dogs (Roberts and Pitts 1952). Similarly all the active cortical hormones have been found to have some effect in depressing the urinary Na^{24}/K^{42} ratio of adrenalectomised rats (Simpson and Tait 1952). Since chemical estimations of the corticoids in adrenal venous blood have shown Compound F and Compound B (corticosterone) to be by far the major secretory products of the adrenal cortex of many mammalian species (Nelson et al. 1950, Hechter et al. 1951, Bush 1951) it has appeared to some (see Sayers 1950) unnecessary to postulate the secretion of a specific "mineralocorticoid" or "salt-retaining hormone" by the mammalian adrenal cortex.

However Selye's comprehensive theory of the existence of "diseases of adaptation" (Selye 1950) depends at least in part on the postulate that the adrenal cortex secretes a mineralocorticoid distinct from and antagonistic in action to the glucocorticoids. Furthermore the glucocorticoid "cortisone" is not fully effective in controlling Addison's disease (Conn, Fajans, et al. 1951, Forsham 1951), nor is it as effective as whole adrenal extract in correcting various deficiencies of adrenalectomised animals (Ingle et al. 1952).

Many objections to the theory of mineralocorticoid secretion by the adrenal were made on the grounds that the actual secretion of desoxycorticosterone (deoxycortone) had not been demonstrated and that this substance was possibly only an artefact in adrenal gland extracts (Dobriner 1952). At the time no other potent mineralocorticoid was known.

The whole question became more complex when it was discovered (Grundy, Simpson, and Tait 1952) that by far the greater part of the "salt-retaining activity" of whole-beef adrenal extract was contained in a hitherto unknown substance of high potency, which could only be separated from "cortisone" by prolonged chromatography. We wish to present evidence in this communication that a similar or identical substance is actually secreted into the blood-stream by the adrenal of the dog and the monkey. It thus appears to be an active hormone of physiological significance and not only a component of gland extracts or simply an artefact.

METHODS

Monkey.—The isolated left adrenal of a 6·35 kg. rhesus monkey was perfused with blood by a technique similar to that of Vogt (1951) and the effluent blood collected in an ice-cooled flask. The blood was extracted at the end of the experiment with ethyl acetate and the extract purified and concentrated by washing quickly with cold N/5 Na$_2$CO$_3$, water, distillation, and partition between petrol and 70% ethanol. The final extract was divided into several parts and fractionated by paper chromatography (Bush 1952). The content of α,β-unsaturated ketonic steroids was determined by their fluorescence reaction with NaOH in two fractions of the extract and the position of "cortisone" on the chromatogram was marked with a pencil. The remaining fractions were run on the same chromatogram but not treated with NaOH. The region of the chromatogram containing the cortisone from these fractions was eluted with ethanol, and the ethanol eluate was evaporated and assayed (table I) by the method of Simpson and Tait (1952).

Dog.—Blood from the left adrenal vein of a 21·5 kg. bitch was collected in vivo under pentobarbitone anæsthesia and after evisceration (Vogt 1943). The splanchic nerves were intact. The blood was extracted and was fractionated by chromatography.

The whole of a chromatogram run in the system toluene : methanol : water (100 : 75 : 25 by volume) was divided into regions and assayed in parallel by the sodium/potassium ratio assay and the fluorescence reaction with NaOH.

A measured portion of the cortisone fraction of the blood extract was acetylated and chromatographed with the benzene : formamide system of Burton et al. (1951).

RESULTS

The results of the two types of assay when applied to these extracts of adrenal blood are given in table I. It is seen that the "cortisone spot" on the chromatogram of the monkey's adrenal blood extract contained 1–2 μg. of cortisone, which would be equivalent to 0·2 μg. deoxycortone in the mineral ratio bioassay used. However, the biological activity of this spot when assayed in the adrenalectomised mouse was equivalent to that of 15 μg. deoxycortone and could not be accounted for by the small amount of cortisone present in the extract.

A more complete study was made of the extract of dog adrenal venous blood. In this experiment the whole

TABLE I—RESULTS OF BIOASSAY OF "E FRACTION" OF 45 MIN. PERFUSATE OF ISOLATED MONKEY ADRENAL GLAND

Substance injected	Dose per rat	No. of animals	Na^{24}/K^{42} urinary ratio
10 % alcohol ..	0·1 ml.	13	3·527 ± 0·357*
E fraction of perfusate	1/30th of total in 0·1 ml. 10 % alcohol	8	2·868 ± 0·387
E fraction of perfusate	1/15th of total in 0·1 ml. 10 % alcohol	8	2·280 ± 0·110
Adrenal extract ..	0·01 ml. in 0·1 ml. 10 % alcohol	8	2·010 ± 0·169
	0·02 ml. in 0·1 ml. 10 % alcohol	7	1·451 ± 0·130

Adrenal extract employed was equivalent to 140 µg. deoxycortone.

$$* \text{S.E.} = \sqrt{\frac{d^2}{n(n-1)}}$$

chromatogram was divided into regions and each assayed for mineral activity. Table II shows that no activity was found in the region occupied by compounds more polar than Compound F, and that the activity in the regions occupied by Compound F and Compound B could be completely accounted for by the amounts of these substances determined chemically. Again, however, the activity of the cortisone region was equivalent to 56 µg. deoxycortone whereas only 15 µg. of cortisone was determined chemically. This amount of cortisone alone would have an activity equivalent to 1 µg. deoxycortone only. No other region of the chromatogram was found to possess salt-retaining activity.

The region of the chromatogram containing cortisone was acetylated and the product chromatographed. The chromatogram was eluted in three parts: (*a*) from the origin to cortisone acetate; (*b*) from and including cortisone acetate to the position of Reichstein's S acetate, which was run parallel with the extract; and (*c*) from Reichstein's S acetate to the front. Appreciable activity after hydrolysis was found in fraction (*c*) which does not include cortisone acetate. This corresponds with the behaviour of the acetyl derivative of the potent mineralocorticoid found in the adrenal extract 'Eucortone' (Grundy, Simpson, and Tait, 1952, Grundy, Simpson, Tait, and Woodford 1952).

DISCUSSION

The above evidence suggests that both the isolated perfused adrenal, and the adrenal in vivo, of two mammalian species can secrete a highly potent mineralocorticoid similar to if not identical with that previously found in adrenal gland extracts. The great activity of this substance would explain why it has not been detected previously by the chemical methods used for examining adrenal venous blood. Table II shows that even when the secretion-rate of the two principal glucocorticoids was high (in the dog) this substance accounted for more than half the total salt-retaining activity of the total adrenal secretion. Whether this relation holds at low secretion-rates or in other conditions remains to be seen.

TABLE II—MINERAL ACTIVITY OF FRACTIONATED DOG ADRENAL PERFUSATE

Fraction number	Region of chromatogram	Amount of known corticosteroids in region	Expected mineral activity from known steroids in region	Actual mineral activity found in region
1	From and including origin to 17-hydroxycorticosterone (Compound F)	0	0 µg. deoxycortone	0 µg. deoxycortone
2	From and including Compound F to cortisone	225 µg. F	20 µg. deoxycortone	20 µg. deoxycortone
3	Cortisone region	15 µg. E	1 µg. deoxycortone	56 µg. deoxycortone
4	Corticosterone region	65 µg. B	10 µg. deoxycortone	15 µg. deoxycortone * 0 µg. deoxycortone
5	Deoxycortone region	0 µg. deoxycortone	0 µg. deoxycortone	0 µg. deoxycortone *

* Fractions 4 and 5 were tested in a different assay from fractions 1, 2, and 3. The cortisone area was found to have comparatively high activity in both assays.

These quantities represent a quarter of total 18 minutes adrenal perfusate. Deoxycortone acetate was used as a standard.

There is no similar evidence that an unknown very active glucocorticoid is secreted by the mammalian adrenal. The secretion-rate of Compound F and/or Compound B is sufficient to account for the results of Vogt using the Selye-Schenker assay, and of Brownell using the liver-glycogen deposition assay (Bush 1951). If, as in table II, we assign these two sorts of biological activity to the compounds secreted by the adrenal in the dog experiment, it is clear that this so far unidentified substance is a biologically significant secretory product of the adrenal cortex and can be reasonably described as a mineralocorticoid. It should be emphasised that if this substance is secreted by the human adrenal, significant changes in the rate of its urinary excretion could not be discovered by any of the usual analytical methods. For instance, Davis (1952) has suggested, mainly as a result of histochemical examination of adrenal glands, that there is adrenal dysfunction in essential hypertension. Hertzel et al. (1952) from a study of glucocorticoids and reducing steroids in the urine of such patients, have found no evidence for this. Our findings indicate that no conclusions can be drawn from these latter estimations, for the active mineralocorticoid such as is secreted by the adrenal gland of monkey and dog would not have been detected. In particular the "benzene : water partition" technique (Talbot et al. 1945) would achieve no separation of this compound from the glucocorticoids found in urinary extracts.

The excessive secretion of salt-active corticosteroids has been suggested as a factor in the ætiology of a wide variety of human diseases (Selye 1950), including rheumatoid arthritis and essential hypertension, and more recently and specifically as a possible cause of toxæmia of pregnancy (Masson et al. 1952). These theories have been questioned on the grounds that deoxycortone, the only known highly salt-active steroid, has not been found to be secreted in physiologically significant amounts by the mammalian adrenal gland (Sayers 1950, Rosenberg et al. 1952). Our findings suggest that the ætiology of such diseases must be reconsidered on the basis that it is probable that a mineralocorticoid is secreted by the mammalian adrenal gland.

SUMMARY

Extracts of adrenal venous blood from a monkey and a dog have been shown to contain a substance very active in its effect on the urinary Na^{24}/K^{42} ratio of adrenalectomised rats. The effect is similar to that previously obtained with extracts of adrenal gland.

Evidence is presented that this substance is secreted in biologically significant amounts and can be reasonably described as a mineralocorticoid.

Reviews of Books

Foetal and Neonatal Pathology

J. EDGAR MORISON, M.D., B.SC., reader in pathology, Queen's University, Belfast; pathologist, Royal Victoria Hospital, Belfast. London: Butterworth. 1952. Pp. 366. 50*s.*

THIS book, which gives a résumé of present knowledge of fœtal and neonatal pathology together with copious references, is on the whole a well-balanced review of a remarkably wide field. Though it is not easy reading, pædiatricians and pathologists will value it as a work of reference. Whether it will appeal equally to the general practitioner, who is specially mentioned on the dust-cover, is more doubtful, but Dr. Morison has certainly succeeded in what he describes as "an attempt to provide a basis for the study of disease in the fœtus and newborn infant."

The book is divided into three sections—disturbances of prenatal life, adaptation to extra-uterine existence, and infections in fœtal and neonatal life. The description of defence mechanisms in the fœtus and newborn infant might perhaps have been given more than ten pages in view of its outstanding importance, and the subject of immunity (which does not appear in the index) treated with less breathless haste. On the other hand, many of the sections are outstandingly good, though Dr. Morison has been careful not to let his personal interests upset the balance of the whole. There remains much that is still obscure or speculative in neonatal pathology, and this book should stimulate further investigation. The diagrams are well chosen and clear, but the reproduction of some of the photomicrographs might be improved.

Clinical Use of Fluid and Electrolyte

JOHN H. BLAND, M.D., assistant professor of medicine, University of Vermont College of Medicine. Philadelphia and London: W. B. Saunders. 1952. Pp. 259. 32*s.* 6*d.*

Companionship of Water and Electrolytes in the Organisation of Body Fluids

Lane Medical Lectures. JAMES L. GAMBLE, M.D. California: Stanford University Press. London: Oxford University Press. 1951. Pp. 90. 20*s.*

IT is only since the war that the development of flame photometry has made possible the rapid and easy determination of inorganic ions in body-fluids. The complete biochemical picture now obtainable has increased interest in disturbances of electrolyte balance. There can be no doubt of the importance of the subject when we observe the recovery of anuric patients or watch easy postoperative recovery from abdominal operation instead of the continued and excessive vomiting which often imperilled life.

Dr. Bland's book is a lengthy and complete discourse on the whole subject, ranging from the use of mercurial diuretics and low-salt diets in heart-failure to problems of fluid-balance in pædiatrics and geriatrics. The book is well documented, but it shows signs of haste in preparation. Fig. 7, for instance, is repeated in fig. 47.

In his Lane lectures Dr. Gamble describes fully dehydration and parenteral-fluid therapy and gives special attention to the problems arising in infancy. But even the greatest authority may have a blind spot, and his description of the respiratory adjustment to acidosis is confusing.

Leptospirosen

Klinik und Epidemiologie von Weilscher Krankheit, Feld-, Ernte- und Sumpffieber, Schweinehüterkrankheit, Canicolafieber, Reisfeldfieber, und andern Leptospireninfektionen bei Mensch und Tier. OTTO GSELL, director of the medical clinic, Canton Hospital, St. Gallen. With an appendix on Bacteriological and Serological Methods by E. WIESMANN, director of the Canton Bacteriological Institute, St. Gallen. Berne: Huber. 1952. Pp. 323. Sw. Fr. 28.

Dr. Gsell is an acknowledged authority on the clinical and epidemiological aspects of leptospirosis. His own observations in Switzerland on the so-called benign forms have added notably to our knowledge of these diseases, and his example and enthusiasm have stimulated many other workers to carry out investigations. Here he gives us a well-documented review, with a bibliography of leptospirosis in general, and develops and explains the conclusions he has drawn from his own experience.

The physician, he thinks, should look on all leptospiral infections as fundamentally the same. It is then possible to divide them broadly into two clinical groups—the benign (non-icteric) and the icteric (often malignant) forms. In the icteric group the prognosis depends, not on the degree of liver damage, but on the extent of the accompanying nephritis, intoxication, and circulatory involvement. Though certain species (e.g., *Leptospira pomona* and *L. grippotyphosa*) usually produce a comparatively mild illness, they can on occasion give rise to very severe disease. In his clinical description Gsell therefore focuses attention primarily on the symptoms which are common to all forms: the sudden onset, high fever often biphasic in type, myalgia, meningismus, renal involvement, reduced blood-pressure, injected conjunctivæ, and rashes. Depending on the severity of the attack, and the organs or tissues chiefly affected, the symptoms may be predominantly renal, hepatic, meningeal, typhoid, or purely febrile. As there is no specific treatment, management depends on the clinical condition of the patient, and not on the species of leptospire producing the disease.

For the epidemiologist such a broad division is insufficient. In general, each species of leptospire has its own characteristic carrier-host, and the differing habits of the animals greatly influence the mode of transmission to man. Thus very different measures would be required to prevent transmission from sewer-rats, field-mice, pigs, and dogs; and the occupational, seasonal, age, and sex incidences of the various forms of leptospirosis are also influenced by the type of carrier animal. In the extensive section on epidemiology Gsell therefore deals with each of the more important species separately, and this practical approach has much to commend it.

In an appendix on the bacteriological and serological methods used in the investigation of leptospirosis, Dr. Wiesmann gives full details of techniques and comments usefully on the interpretation of serological reactions.

Diseases of the Nervous System (7th ed. Edinburgh: E. & S. Livingstone. 1952. Pp. 365. 24*s.*).—This is the seventh edition of Dr. F. M. R. Walshe's book to appear since 1940, which shows how popular it has been with the medical student and general practitioner for whom it has been written. Its girth has increased since the first edition, but its scope has not changed and it remains an unrivalled account of the best approach to a neurological case and description of the more common neurological disorders. The production of the book is good, and considering the number of excellent illustrations of pathological specimens and X-ray pictures, the price is remarkably low by today's standards.

THE LANCET

LONDON: SATURDAY, AUGUST 2, 1952

Charges for Pay-beds

If the new tables of hospital costs[1] are used for calculating the charges made for pay-beds, these charges will rise yet further. In one of the London specialist hospitals the private patient is already asked to pay £27 8*s*. a week, and such figures may soon be the rule rather than the exception. Many people who have been willing to take a private bed will find that they can no longer afford to do so.

By paying his doctors and by paying the hospital, the patient in the private bed gains certain privileges which he may value highly. First, if he is given a room of his own, he has privacy, which he may like for its own sake or because it enables him (if he is not too ill) to see more visitors, attend to his affairs, or even conduct his business by telephone and correspondence. Secondly, being admitted privately under the care of a particular member of the hospital staff, he can be reasonably sure that he will be treated by the doctor of his choice and not handed over to an assistant. Thirdly, by making these private arrangements, he may hope to be admitted and treated at a time that suits him—probably much sooner (if he wishes) than some other patient who is put on the non-urgent waiting-list of cases for the ordinary wards. The idealist may object to anyone being able to buy these privileges: privacy and early treatment may be as much desired, he will say, by the worn and nervous young mother from Seven Dials as by the woman with unbreakable social engagements in Belgrave Square; and in a National Health Service the criterion should be need not money. The answer to this, however, is that these paying patients are *not* being treated under the N.H.S. and are making no claim on it, since they pay for everything they get—and indeed something in addition. This answer would become less valid if (as has been proposed by the British Medical Association's Amending Acts Committee[2]) pay-beds were partly paid for out of N.H.S. funds; for it would then appear that, within the service, money would buy additional and substantial privileges denied to those who could not afford them. As things have stood since 1948, and should continue to stand, no privileges can be bought within the service (except the amenity bed, for which a relatively small charge has been made); and people who want privileges and are prepared to pay for them are treated under separate arrangements though not necessarily in a separate building. Egalitarians may say that it will be better for the community when everybody goes to the same schools, and occupies the same hospital beds, but we have not yet reached so egalitarian a society that people with money can be prevented from purchasing the services they want, when they harm no-one else by doing so. Before the N.H.S. Act was introduced, the well-to-do patient (and even the not so well-to-do) could purchase the advantages of a private bed from most of our big hospitals, and it would have been wrong for the service to deprive him of the right to do this. As the amenities of the public wards improve, fewer and fewer people will wish to pay for privacy, which (because it may breed boredom and depression) is quite often against their real interests. But it would again be wrong to hasten this development by imposing penal conditions on those who do not change their attitude as fast as the social reformer would like. Reform would be a far more popular process if it never removed anything good until it had provided something better.

Our opinion, then, is that hospitals should continue to offer private beds to people who want to be treated privately; that they should charge the patient the full cost of maintaining a private bed; and that the N.H.S. should neither penalise the private patient, nor try to make a profit out of him, by charging him more than the true cost. Under the present system he has to pay what is supposed to be the average weekly cost of a public bed in the hospital, plus 25% to cover the extra labour of attending to him individually in a small ward, the larger space he occupies, and any additional amenities he may enjoy. Now that the basic cost of the public bed has become so high, this 25% is far from being a negligible figure and ought to be reconsidered: logically perhaps the additional charge to paying patients should be the same as the charge made when a public patient transfers to an amenity bed—a charge which has lately been raised to the uncomfortably high figure of 12*s*. a day. More important, however, is an equitable revision of the method of calculating the true cost of a private patient; for the way in which this is now done is far from satisfactory. The most conspicuous fallacy is one to which we have already drawn attention.[1] A substantial but very variable proportion of the income of many hospitals is spent on their outpatient departments, and, now that some of these have become major centres of consultation and investigation, this proportion is often underestimated by the arbitrary decision that the cost of each outpatient attendance is to be reckoned as a fifth of the cost of one inpatient day. Whenever this is in fact an underestimate of the cost of outpatients, the returns will show the expenditure on inpatients as higher than it really is. Thus there is good reason to think that the cost of beds as stated in the report lately issued, which is likely to be used by hospitals in deciding their pay-bed charges, usually includes a subsidy to the outpatient departments; and it is unfair that private patients, who are outside the service, should be expected to share in subsidising departments which hardly any of them have ever used. Another question that needs further thought is whether the charge made for a private bed should be based on the weekly cost of all the public beds in the hospital or only on the cost of the occupied beds. Calculation of the cost of a hospital bed is a complex piece of accountancy, and a wide range of figures can be produced. A fair interpretation of the Act would permit a substantial reduction of some of the present charges, which would not only be just to the paying patient but also be sound economics for the N.H.S.

---

[2] *Brit. med. J.* 1951, ii, suppl. p. 141; see *Lancet*, 1951, ii, 710, 731.

If an effort were made to ascertain the actual cost of private patients at each hospital, there would be less risk of the charges becoming prohibitive. It should be borne in mind that if the beds become too expensive, and are not fully used, the N.H.S. will lose financially.

Treatment of Bacterial Meningitis

PÆDIATRICS offers no greater satisfaction than the successful treatment of a child with bacterial meningitis. Early and precise diagnosis followed by planned and vigorous treatment lead directly to an earned reward: the sight of a child rescued from death or idiocy and restored to lasting health.

The spectacular multiplication of chemotherapeutic agents in this field has tended dangerously to obscure the essentials of treatment. We have already urged[1] that in hæmophilus meningitis early diagnosis, intensive chemotherapy, and the thorough treatment of complications are the triune foundation of success. Dr. HATTIE ALEXANDER, in her admirable contribution to the fifth volume of Advances in Pediatrics,[2] now asserts that these three principles are equally important in all types of meningitis. She shows that, in general, the older drugs have not yet been surpassed by the new antibiotics. Sulphadiazine for meningococcal meningitis, penicillin for pneumococcal meningitis, and streptomycin for tuberculous meningitis, remain the weapons of first choice. Improved results have sprung, in Dr. ALEXANDER's words, from "optimal therapy rather than minimal therapy," and she cites the work of DOWLING and his colleagues[3] as an example. These workers, with a generous boldness native to their country, recommend 12 million units of intramuscular penicillin a day as the basic dose for an infant with pneumococcal meningitis. This may be excessive; but those who have seen the results of partial treatment will agree that there is no place for niggling dosage: there is certainly no economy in saving on drugs if the outcome is prolonged illness with a risk of mental defect. Even with this huge dosage, it may be noted, penicillin must still be given by the intrathecal route. ALEXANDER found that therapeutic levels[3] of penicillin in the cerebrospinal fluid (C.S.F.) were not attained for 8–12 hours, although the meninges were acutely inflamed and 1 million units was being given every 2 hours. Dr. ALEXANDER recommends that an adjuvant chemotherapeutic drug should be administered routinely in each form of meningitis both as a secondary attack against the invader and to prevent the emergence of drug-fast strains. Most workers in this country endorse such a practice. The number and the splendour of the new antibiotics may, however, tempt the unwary into a blind polypharmacy, with results possibly disastrous to the patient and certainly valueless in the trial of the new agents. There is still no indication for giving more than two drugs in any form of meningitis.

In the treatment of complications there have been three recent advances. Firstly, the Waterhouse-Friderichsen syndrome has been treated with cortisone with apparent success,[4,5] and Dr. ALEXANDER confirms its value. The number of treated cases is, however, small, and the antemortem diagnosis of bilateral adrenal hæmorrhage is notoriously difficult. Meanwhile, doctors treating meningococcal infections will do well at first to chart the blood-pressure every fifteen minutes.[6] They may thus catch a case of adrenal failure in the early stages, and they will certainly obtain useful evidence of the pressures to be expected in septicæmic children without adrenal damage. Secondly, subdural effusions of fluid have begun to be a relatively common complication of purulent meningitis,[7] especially in centres where the intrathecal route of medication is avoided; and in some patients aspiration of the fluid has been found to relieve persistent fever or focal neurological signs. Finally it has been established that convulsions complicating purulent meningitis are both ominous signs and dangerous per se[8]; routine prophylaxis with anticonvulsants and vigorous treatment of emergent seizures are integral parts of successful treatment.

None of the newer remedies has yet proved more valuable than streptomycin in the treatment of tuberculous meningitis, though some early results recorded by Dr. SWEETNAM and Dr. MURPHY in our last issue[9] supported the hope that isoniazid is going to be useful in these acute illnesses. A recent advance has been, paradoxically, a brilliant reversion to KOCH's treatment with tuberculin. The intrathecal injection of the purified protein derivative (P.P.D.) has resulted in dramatic cures of children apparently moribund.[10] This method of treatment, and indeed the treatment of tuberculous meningitis by any method, is not for the tyro: the pitfalls are many, and the best results can be won only by a team working in a special centre. Delayed diagnosis remains the first cause of failure. P.P.D. was, of course, introduced by SMITH and VOLLUM primarily as a research tool; and their elegant experiments have already thrown fresh light both on the nature of tuberculous sensitivity and on the intimate nature of bacterial inflammation.[11] Their work, which sprang from the contemplation of unexplained spikes on the graphs of C.S.F. changes in affected children, is a pleasing example of clinical research repaying some of its debt to the basic sciences.

Dr. ALEXANDER's review makes it plain that, although many pockets of resistance remain, the broad sweep of conquest over bacterial meningitis is within sight of completion. Yet, for the physician, the battle begins afresh each time a child presents with a stiff neck. Failure to diagnose with speed and to treat with vigour carries unchanged penalties; and "a victory is twice itself when the achiever brings home full numbers."

Œsophageal Hiatus Hernia

HERNIATION of part of the stomach through the œsophageal hiatus of the diaphragm is a fruitful source of errors in diagnosis. Though this disorder is being detected increasingly often,[1] it is still commonly overlooked; HARRINGTON[2] found in his series an average of three previous erroneous diagnoses—the commonest being gall-bladder disease, peptic ulceration, carcinoma or stricture of the œsophagus, heart-disease, anæmia, hyperacidity, and intestinal obstruction. On the other hand, it is no less easy to fall prey to the opposite danger "and repair a hernia for gall-bladder trouble."[3]

In most cases hiatus hernia is probably due, not to developmental error, but to factors operating in adult life—notably laxity of the tissues at the hiatus with advancing age and increased intra-abdominal pressure from such causes as pregnancy, obesity, tumours, coughing, and belching. HARRINGTON[4] examined the œsophageal opening in 500 consecutive abdominal operations and found that in 33% more than one finger could be inserted between the diaphragm and the œsophageal ring. VON BERGMANN[5] emphasised that the longitudinal fibres at the lower end of the œsophagus were continuous with those of the stomach; and he suggested that herniation might be due to a vasovagal reflex from the upper abdominal viscera. GILBERT and his associates[6] confirmed that in dogs stimulation of the vagus, directly or reflexly from the abdominal viscera, caused shortening of the œsophagus and pulling up of the stomach—an effect that was abolished by atropine. They found, too, that more than half of their patients had some possible source of such a reflex. Congenital short œsophagus with a thoracic stomach is rare; but herniation may sometimes be caused by secondary shortening from inflammation and subsequent cicatricial contraction.

The two main forms of hiatus hernia are the œsophagogastric and the para-œsophageal—termed by ALLISON[7] the sliding and rolling types. In the first type the stomach slides through the hiatus with the œsophagus leading, and the incompetent sphincter allows regurgitation of acid gastric juice. In the rolling type the sphincter is normal and there is no regurgitation. The two types may be present together. The hernia may present only intermittently and may disappear when the patient stands; and likewise symptoms may be constant, intermittent, or completely absent. The condition is usually found in middle-aged overweight women of nervous disposition who commonly have some other abnormality—for example, of the stomach or gall-bladder. HURST[8] remarked on the influence of fatigue and nervous factors in precipitating symptoms. These symptoms have been well described by NICHOLSON[3] in an account of 62 cases. With the sliding type they may consist of belching, fullness after meals, and epigastric discomfort; and if the disorder is complicated by reflux œsophagitis there will be intense burning pain behind the lower end of the sternum, often coming on in the middle of the night and radiating to the back, the arm, the ears, the palate, and vaguely to the neck. With the para-œsophageal hernia, on the other hand, œsophagitis does not occur; and the symptoms consist in flatulence, "wind around the heart," "asthma," anæmia, and attacks of severe upper abdominal pain and of vomiting with remissions. There may be slight dysphagia, and a gastric ulcer may develop near the cardia. Dyspnœa and cough may result from a large hernia in the posterior mediastinum.

VON BERGMANN[5] first pointed out the similarity of the pain of hiatus hernia to that of angina pectoris; and possibly reflexes from the hernia may cause true angina from coronary insufficiency, for GILBERT and his colleagues[9] showed experimentally that distension of the stomach resulted in decreased blood-flow through the coronary circulation. VAN DELLEN,[10] moreover, found typical electrocardiographic evidence of coronary insufficiency in records taken while herniation was present, whereas while the hernia was absent the electrocardiogram was normal. On the other hand, anginal pain may be initiated by distension of the herniated part of the stomach or œsophagus since the nerve pathways are the same. NUZUM[11] found that the prevalence of hiatus hernia in otherwise normal people had been variously estimated at figures ranging from 0·13 to 8·9%. Of 100 patients with angina pectoris whom he studied 25 had a hiatus hernia; whereas of a control group of 957 patients subjected for various reasons to radiographic examination of the gastro-intestinal tract only 12% had such a hernia. The lesson seems to be that cases of angina pectoris, especially with unusual symptoms, should be investigated for a hiatus hernia. Both in such cases and in others where atypical upper abdominal symptoms suggest the possibility of a hernia, the radiologist should be asked to make a special examination for it.

Treatment in the first place should always be medical; for medical treatment, together with reassurance as to the absence of heart-disease, often suffices to relieve symptoms. When œsophagitis is present the régime should be similar to that for peptic ulceration. Late meals should be avoided, and the patient should be advised to sleep propped up in bed or with the head of the bed raised on a block, and, as far as possible, to avoid bending. Œsophagoscopy is necessary if there is dysphagia or suspected ulceration, in order to place the diagnosis beyond doubt. CLERF and his colleagues[12] have found that many patients are relieved by dilatation of the œsophagus when this is narrowed, or by the application of silver nitrate when ulceration is present. Many years ago SAUERBRUCH[13] reported good results from interruption of the left phrenic nerve. This method has since been followed by many surgeons; and PICKHARDT and his colleagues[14] are convinced that in older patients it is the most satisfactory treatment. If a stricture or severe ulceration has developed, resection of the affected portion may be necessary. Usually, however, *reduction of the hernia and repair of the defect is the* surgical treatment of choice; and this should preferably be carried out by the transthoracic approach.

Annotations

THE RIGHT PLACE FOR THE CHILD

GROWING up, like navigation, is always a difficult art. All agree that a child usually masters it best when living in his own home surrounded by his own family; but if he is deprived of this favourable situation, then, the experts say, he will do better in the home of congenial foster-parents than in an institution, however benignly conceived. By an extraordinary suspension of the well-known laws of cussedness, it so happens that in this case the best is also the cheapest. The Select Committee on Estimates, who have just reported on child care,[1] find that the estimated expenditure by local authorities in England and Wales for children in their care for 1952–53, is £1 8*s*. 10*d*. weekly for a boarded-out child, £2 9*s*. 2*d*. for a child in a voluntary home, and £5 5*s*. 1*d*. for a child in a local-authority home. In Scotland the cost of boarding out is a little lower, and the cost of maintaining a child in a voluntary or local authority home a little higher. It might reasonably be supposed that in these hard times boarding out would be widely preferred to institutional care for children; but in fact the committee found great variety of practice up and down the island. Thus in Cheshire 59% of the children in care are boarded out, in Staffordshire 49%, in Hampshire 33%, and in Bradford 23%; the lowest figure was 18% and the highest 77%. Scotland has boarded out 59% of children since 1950, but there is as wide a variation between different Scottish local authorities as between authorities in England and Wales. It is worth noting, however, that Glasgow, with nearly 3000 children in care, manages to board out 70%.

These divergences of practice reflect differences of opinion on the proportion of children in care who are fit for boarding out. Some think that only about half are suitable; others, by taking thought, have raised the percentage greatly in a matter of a few years. Thus Bournemouth, where only 21·6% were boarded out in February, 1949, was boarding out 82·1% by March, 1952. The Home Office believes that it should be feasible to board out between half and two-thirds of the children in care in England and Wales.

Of course there will always be some children who, because of physical or mental disability, need the constant care of trained staff. Apart from these there are children who have been neglected or ill-treated who perhaps need building up in the friendly unemotional atmosphere of a children's home or residential nursery before they are fit for the rough and tumble of ordinary home life. Then a child who has been sent back from a foster-home for one reason or another (or perhaps because a foster-parent has fallen ill) may need more training in social behaviour, or some reassurance to restore his shaken confidence, before he is tried again. Difficult and maladjusted children may be unacceptable to, or unmanageable by, the usual types of foster-parents; and it is also sometimes difficult to find foster-parents for coloured children. The committee rightly object to a Home Office statement that 'institutionalised' children "would find too difficult the uprooting from a large community and adjustment to ordinary family life." What, indeed, can be said for an upbringing that unfits one for ordinary manners and customs? It is a different matter, however, when the good house-mother in a residential home proves unwilling to part from a child with whom she has made a successful parent-child relationship—a situation on which the committee might have commented more fully. Some of these homes are small, and run on the family pattern, taking some dozen children of both sexes ranging in age from 2 or 3 to 12 or 15. The house-mother is often married, her husband, like other fathers, going out to work daily; and the children go to the local school and join in the local activities. With so much family life going on, both the child and the house-mother may wonder what he has to gain by going into a foster-home. Finally there is the thorny question of opposition from the real parents; and if there is a chance that the child may return home before long, their objections must be taken into account. Parents sometimes object to foster homes because they fear alienation of the child's love, and sometimes because they honestly think the child would be better cared for in an institution. The London County Council have found that boarding out against the wishes of parents so often ends in trouble for the child (because of his divided loyalties) and annoyance for the foster-parent that they no longer board children out without the parents' consent. A troublesome parent may make a foster-parent withdraw from the panel, and this, the council say, influences the recruitment of new foster-parents in the neighbourhood. On the other hand, very little has been done so far to advertise the need for foster-parents, and if unsuccesful boarding out acts as adverse propaganda, successful boarding out has the opposite effect. Glasgow, for example, has records of boarding out going back for 170 years, and the tradition is maintained and spread by the foster-parents themselves. London, which did not start boarding out seriously until 1949, had 18·2% of its children in foster-homes by the end of that year, and had only raised the proportion to 24·4% by the end of 1951.

The committee feel that the need for foster-homes should have much wider publicity. They recommend that the Home Office should renew their instructions to local authorities to regard boarding out, with due safeguards, as "the primary objective." Regular returns should be made to the Home Office, and to each children's committee, giving the name of every child not boarded out, and the reason why. They also think more thought should be given to training unsuitable children so that they may become fit for boarding out; and it might be arranged for authorities with difficult areas to board out some of their children in the areas of authorities more fortunately placed. Certainly there must be a vast undiscovered pool of willing foster-parents in the country who have never offered their services because the idea has never been presented to them. A few clever posters might well have an astonishing response.

ERYTHROMYCIN: ANOTHER ANTIBIOTIC

THE antibiotics in current use can be roughly divided into those whose action is relatively specific and those with a broad spectrum of activity. Of the broad-spectrum antibiotics, the three most effective are aureomycin, chloromycetin, and terramycin; but a versatile newcomer now threatens their supremacy. McGuire and his colleagues[1] isolated this substance in crystalline form from a strain of *Streptomyces erythreus* (Waksman) in a soil sample collected in the Philippine Archipelago; it has been named erythromycin, with the trade name of 'Ilotycin' (Lilly). It was significantly active against pathogenic gram-positive organisms and some of the more important gram-negative ones, such as the neisseria, hæmophilus, and brucella groups; it also had some activity against *M. tuberculosis* and other mycobacteria, against rickettsia, viruses of the lymphogranuloma and mouse meningopneumonitis type, *Entamœba histolytica, Trichomonas vaginalis*, and threadworms in mice. Staphylococci resistant to other antibiotics were susceptible.

Erythromycin is a basic compound that readily forms salts with acids; it is soluble in water to the extent of 2 mg./ml., and is extremely soluble in alcohol. The empirical formula is $C_{34-35}H_{60-65}NO_{11-12}$. Its toxicity is very low—mice tolerated single doses as high as 2000 mg./kg. by mouth, and there were no deaths after subcutaneous doses up to 1000 mg./kg., the LD_{50} by subcutaneous injection being about 1800 mg./kg.; no toxic signs were found in mice receiving 1400 mg./kg. by mouth or 700 mg./kg. subcutaneously or intraperitoneally daily for a fortnight. In dogs no signs of toxicity were found after they had taken 0·5 g. twice daily by mouth for a fortnight. Erythromycin could readily be detected in the blood, urine, fæces, and cerebrospinal fluid of the dogs; the method of assay was an adaptation of Rammelkamp's procedure, using group-A streptococci. The blood-level reached its peak about an hour after an oral dose, and the drug could be detected in the blood for about 8 hours. It must be wholly distinct from "actinorubin," a toxic and far less active substance derived from an actinomyces resembling *erythreus*; and should not be confused with erythrin, an antibacterial substance obtained from red cells.

Preliminary clinical trials are described as "encouraging." By mouth, erythromycin was effective against streptococcal and pneumococcal infections and virus pneumonia.

COLD IN KOREA

IT has been calculated that cold-injury casualties among the American troops in Europe during the winter of 1944–45 were equivalent to the loss of the effective fighting strength of 12 infantry divisions for fifty days. Accurate or not, this calculation illustrates the importance of cold for modern armies.

A report by Orr and Fainer [1] on cold injuries in Korea during the winter of 1950–51, as well as providing useful clinical data, contains much ecological information. Over 4000, or more than half, of the cold casualties evacuated from Korea were admitted to a special cold-injury unit in Japan. In addition to those evacuated primarily for frost-bite, there must have been many wounded men whose injuries were substantially aggravated by frost-bite, but who would not be listed as suffering from cold injury. Some 16% of the casualties so classified were unusual in that they had none of the clinical features regarded as typical of frost-bite, and no history of the feet becoming very cold or numb. Instead there was a gradual onset of stinging and burning of the feet, which showed hyperhidrosis with erythema and maceration of the skin on the soles. Physical irritation from trauma and chemical irritation from long-continued contact with sweat in impermeable footwear were regarded as contributing to this syndrome. A simple classification of frost-bite into four grades of severity was adopted. The first degree showed erythema, swelling, and desquamation; the second, vesiculation; the third, damage to the entire thickness of the skin; and the fourth, damage to the entire foot, making amputation necessary. Few or no vesicles were seen in the most severe grade, but large thin-walled bullæ were commonly present just proximal to the zone of worst damage, and their position gave an indication of how extensive an amputation would ultimately be needed.

The report contains a great deal about environmental circumstances; while, in general, little of it is new, the quantitative aspects are valuable. The duration of exposure in 90% of cases was less than twelve hours; the incidence was highest, as might be expected, among troops actually engaged with the enemy; and the rifleman was affected more often than the N.C.O. or the officer. Not only do winter battle conditions preclude the use of artificial sources of heat, but they involve short bursts of activity with profuse perspiration and prolonged immobilisation in the closest possible contact with frozen ground.

Great interest centres around treatment and especially prophylaxis. Here Orr and Fainer come to the melancholy but inevitable conclusion that in winter climates, such as that of Korea, a considerable incidence of frost-bite must be accepted during combat. But the number of casualties can be reduced in various ways, such as the exclusion of highly susceptible men. Negroes are more susceptible than fair-skinned people, and peripheral vascular disease, previous cold injury, and a high cold-hæmagglutinin titre also seem to make things worse. Thorough and prolonged low-temperature combat training is of undoubted value. Improvements in protective clothing are certainly possible: for instance, severe frost-bite rarely attacked those who wore leather mittens or gloves with woollen inner gloves. Dryness is very important, but it was found that where external moisture was excluded by impermeable gloves or boots, endogenous moisture from perspiration became troublesome. However, this difficulty might be overcome by some of the new fabrics or plastics which permit the escape of water vapour while preventing the entrance of liquid water.[2]

In discussing the immediate treatment, Orr and Fainer emphasise the removal of clothing, and the warming of the frost-bitten area by exposure to a room-temperature of 70°–78°F or by putting the patient's hand in his axilla. Brisk rubbing is better avoided, for it may cause trauma. The authors refer to data indicating that rapid rewarming in baths at 98°–103°F is advisable; but even if this is so it would be impracticable in the field. Chilling, rather than heating, of the injured part certainly seems to result in greater tissue loss,[3] and general body warmth is important.

The consideration of this aspect of military surgery cannot fail to arouse a certain thankfulness in those who fought the late war in desert or jungle rather than on steppe or tundra.

TREATMENT OF LARGE ANEURYSMS

FROM the day that it is discovered, an aortic aneurysm troubles the patient either with pain or with the threat of sudden disaster. Most victims die of the disease; for treatment still falls short of what is needed. In John Hunter's time popliteal aneurysms were common enough to attract much surgical attention; and his method of ligation above the first collateral vessel is still one of the basic principles of vascular surgery. But with the aorta the problem is to apply compression without causing rupture. Halsted ligated the aorta experimentally with metal bands, which had less tendency to cut through the wall than a silk ligature, and Blakemore [4] has employed a similar method in abdominal aneurysm.

Arterial grafting might seem the ideal way of dealing with an aneurysm. In the limbs this may prove to be so, but the aorta has only two places at which a sufficient length can be mobilised—below the renal arteries, and between the left subclavian artery and the diaphragm. Lam and Aram,[5] Brock,[6] and Dubost et al.[7] have described successes with this kind of reconstruction. In most cases, however, the lesion is in a stretch of aorta which bears several large and vital branches; and here

the problem is to reinforce the sac. More than seventy years have passed since Morrant Baker enlisted relays of dressers to maintain digital compression of a femoral aneurysm for days on end—apparently with good result. Since then other and less simple procedures have been followed, of which wiring and external strengthening are the most popular. A saccular aneurysm is suitable for the insertion of one or more Colt's umbrellas; the surprisingly large amount of wire which they contain is specially treated to collect thrombus. Patients often gain much relief of pressure pain, and embolic complications are less common than would be supposed. Another method is to introduce one long piece of steel wire through a lumbar-puncture or similar needle. Linton and Hardy[8] have described their experience of this; fusiform aneurysms which would otherwise be inoperable can be filled with 300 feet or more of wire. External application of fascia or foreign material met with little success until the discovery of the fibrosing properties of some forms of 'Polythene' 'Cellophane.'[9] Poppe and Oliviera[10] produced periaortic fibrosis by wrapping the aneurysm with a particular sample of the polymer, which was later shown by Yeager and Cowley[11] to contain small quantities of dicetyl phosphate as the active principle. This substance is sometimes added to the pure solvent cast polythene as a plasticiser. Berman and his associates[12] have shown that in rats injection of this compound into the perivascular tissues will cause intense fibrosis but no toxic effects in strengths several times greater than the 0·9% in olive oil which is the recommended therapeutic dilution. They also describe the results of using periaortic injections of dicetyl phosphate in the treatment of patients with aneurysm of the aorta. In no case could reduction in the size of the sac be shown; but a thick layer of fibrous tissue can be relied on to form and probably to limit the further expansion of the aneurysm. Symptoms were relieved in most of the patients who were followed up, but rupture has been seen. Injection of dicetyl phosphate may prove most useful in combination with other methods; it is particularly convenient in treating obscure or dangerously thin portions of the sac. Bearing in mind the limitations of scar tissue as a surgical material, this substance may become a useful member of the selected team of drugs which the surgeon likes to keep in the theatre.

ULCERATIVE COLITIS AND PREGNANCY

THE incidence of ulcerative colitis is greatest during the child-bearing years; and its presence may give rise to some difficulties in the management of married women who are, or wish to become, pregnant. Pregnancy has a very variable effect on the course of the disease, but it may precipitate both first attacks and relapses. Wittkower[13] found that of 40 patients with ulcerative colitis, 3 first had symptoms of it during pregnancy; and Sullivan[14] reported that in 2 out of 15 cases which he analysed the onset of diarrhœa was related to pregnancy. Feder,[15] Bargen et al.,[16] and Buzzard et al.[17] noted that pregnancy was one cause of relapses in their cases. The difficulty in predicting the effect of a pregnancy on any given case has been shown by Kleckner et al.,[18] who found that of 19 patients with ulcerative colitis who had been pregnant at least once, 5 improved in the course of pregnancy, 4 became worse, and 4 were unaffected; but 3 of the cases which improved relapsed in the postpartum period, while 2 of those which relapsed during pregnancy improved after delivery. In the remaining 6 of the 19 patients the disease first began during pregnancy, particularly the first three months.

Patterson and Eytinge,[19] of Boston, have recently reported on 16 patients with ulcerative colitis associated with pregnancy and have divided them into three groups.

> The first group comprised 8 patients who became pregnant while the disease was active (though in no case was the course fulminating). Of these patients 4 thought that their colitis was improved by pregnancy, 3 thought that the disease was aggravated both during and after pregnancy, and the remaining patient was unaffected. In 2 cases the disease became much more severe; 1 of these patients died while being prepared for ileostomy, and the other is likely to undergo an ileostomy. The colitis had no obvious effect on the pregnancy. In a total of 18 pregnancies there was 1 spontaneous abortion and 1 fœtal death, but both these mishaps were thought to be unrelated to the disease.
>
> In the second group were 3 patients who became pregnant while their colitis was in remission. Of these, 2 thought that pregnancy had no effect on their condition, while 1 believed that her symptoms were aggravated. (Tumen and Cohn[20] have also described 3 cases in which the patients went uneventfully through pregnancy during a remission of the disease.)
>
> The third group consisted of 5 patients who developed ulcerative colitis during pregnancy. All 5 were acutely ill, and the entire colon was involved. 1 patient died in the sixth month following a miscarriage, and another required ileostomy as a life-saving measure. (Tumen and Cohn likewise observed 3 cases of colitis beginning during pregnancy, in all of which the disease was extremely severe and required ileostomy, followed in 1 by colectomy.)

From the small amount of evidence it appears that during a remission of ulcerative colitis there is a good chance that a patient may be unaffected by pregnancy. In considering whether a patient in remission should be permitted to undertake a pregnancy, the factors to be taken into account include the duration of the remission (it would seem unwise to allow pregnancy in a patient who has been in remission for less than a year) and the frequency and severity of previous attacks. In addition, remembering the important part which psychological factors may play in the course of ulcerative colitis, it is important, as Patterson and Eytinge point out, to discover whether the patient really does want to become a mother or whether she is inquiring at the instigation of her husband or to be assured that she cannot have children. Where pregnancy is genuinely desired, to deny it may itself lead to a relapse. In a patient in remission who is already pregnant, the pregnancy may often be allowed to continue; but termination may have to be considered in certain cases, particularly where it seems that the patient could not bear the extra strain imposed by an addition to the family. When the disease is clearly active, pregnancy is better avoided; but Patterson and Eytinge have shown that in these circumstances the disease need not necessarily become worse; so in some cases, especially when the pregnancy is much desired and the disease mild, it may justifiably be allowed to continue.

Mr. O'DONEL BROWNE, master of the Rotunda Hospital, died in Dublin on July 24.

Mr. A. A. GEMMELL has been elected president of the Royal College of Obstetricians and Gynæcologists in succession to Dame Hilda Lloyd. He will take office in October.

INTERNATIONAL CONGRESS OF DERMATOLOGY

THE tenth International Congress of Dermatology was held in London from July 21 to 26, under the presidency of Sir ARCHIBALD GRAY. The attendance was well over a thousand, drawn from 45 countries including the U.S.S.R. The scientific meetings were held at Bedford College, and simultaneous translation into English, French, German, and Spanish was available for the larger meetings.

Addressing a great audience at the congress dinner held at Grosvenor House on July 24, Sir HENRY DALE, O.M., F.R.S., proposed The Future of Dermatology. The founders of the specialty had, he said, pursued industriously the task of classification, and nothing in science was more imposing than dermatological nomenclature. The discovery of the itch-mite was the first recognition of an external organism as the cause of a disease, and dermatologists were cultivating fungi long before the days of Lister. Study of the skin, because it afforded such easy access, had played a large part in revealing the rôle of spirochætes, protozoa, and other organisms in causing disease; and in Professor Hoffmann the congress was able to salute in person the co-discoverer, with Schaudinn, in 1905, of the *Spirochæta pallida*. Dermatologists had been early in the field of morbid histology, and they were helping to write the still unpublished chapters in pathological physiology. Anaphylactic and allergic reactions—representing a perversion of reactions of immunity—formed a basis of their present discussions; and having taken his share in demonstrating the significance of the liberation of histamine, Sir Henry felt some grandfatherly pride in the antihistaminics latterly developed in France. He could safely prophesy (1) that dermatologists would continue to make discoveries of first-class importance, and (2) that there would remain a large number of conditions which they could do no more than identify and palliate.

As the first of five visitors to reply to the toast, Prof. L. M. PAUTRIER (France) spoke of the way in which the study of diseases as they affect the skin has thrown light on their general pathology: among others he instanced tuberculosis and sarcoidosis, and he expressed pleasure at recent evidence of the foresight of colleagues who had applied themselves to research on collagen tissue. Prof. E. HOFFMANN (Germany), in recalling old and famous names, exhorted the young to make the most of their opportunities. Dr. D. M. PILLSBURY (U.S.A.) thought that at times the useful basic knowledge about the skin lagged behind knowledge about other organs whose movements and secretions appealed more to investigators; but in this respect times were changing. He expressed the thanks of those present to their British hosts for overcoming all difficulties and re-creating this international conference: medical problems transcended nationalism, and advance would be easy if men could but grasp the hand of colleagues throughout the world. Two further responses came from Prof. FRANCO FLARER (Italy), who had been delighted by the spirit of freedom in the congress discussions, and the fraternal feeling, and from Prof. GAY PRIETO (Spain).

Prof. H. HAXTHAUSEN (Denmark) proposed the toast of The Ladies' Committee, without whose distractions, he said, "many of us would have collapsed under the heavy burden of scientific discussion." To which Lady GRAY most modestly replied.

The programme included the demonstration of cases on two afternoons, a most creditable selection of disorders being assembled at the Queen Alexandra Hospital, Millbank. A number of films were shown, and throughout the week there was a display of photographs, wax models, microscopical preparations, and books of historical interest. On July 25 the Royal College of Physicians held an evening reception at which members of the congress were welcomed by Sir Russell Brain, the president, and Lady Brain.

Eczema

Since there is still no general agreement on the concept of what constitutes eczema Dr. J. C. BELISARIO (Sydney) suggested that the term be limited to a morphological entity comprising erythema, minute papules, vesicles, pits, and crusts. He outlined the known facts and theories on the pathogenesis of eczema and laid stress on the beneficial effect of an increased oxygen supply in inflammatory skin eruptions.

Dr. D. M. PILLSBURY (Philadelphia) indicated the magnitude of the problem of eczema by stating that more American troops were evacuated from the Pacific theatre on account of skin disease than because of wounds. At least half of the skin sick had some form of eczema. Even in temperate climates, sweat retention played an important part in the aggravation of eczema, notably in atopic dermatitis. The origin of nummular eczema remains obscure.

Prof. G. MIESCHER (Zürich) wondered how far one was justified in regarding all eczema as allergic. The only type in which we had satisfactory evidence of allergy was contact dermatitis of sensitisation. Here the histological appearances were uniformly similar whatever the allergen: there was epidermal spongiosis with an infiltrate of lymphocytes. In dermatitis due to primary irritants one saw foci of pyknotic epidermal cells.

Dr. R. T. BRAIN (London) found skin-testing of very little value in the elucidation of the cause of infantile eczema. Histamine did not appear to play a direct part in the production of eczema. A great deal could be achieved in infants with adequate sedation: control by adrenocorticotropic hormone (A.C.T.H.) or cortisone was often incomplete.

Prof. J. GATÉ (Caluire, Rhône) felt that results of treatment had shown that psychological factors contributed to the pathogenesis of eczema but that they did not explain everything. He had been unable to show the congenital transmission of eczema in experimental animals, and doubted whether circulating antibodies existed in them.

Prof. G. HAGERMAN (Lund) advanced a theory to explain how lymphocytes transmitted epidermal hypersensitivity: according to Andrew and Andrew, lymphocytes were transformed into epidermal cells. At Lund, lymphocytes were being injected intraperitoneally after vital staining and their fate studied in excised skin.

Several contributors emphasised the importance of physicochemical factors in the production of exogenous dermatitis. Dr. D. ANDERSON (London) said that the pH of the skin in normal adults was between 4 and 6: in the axillæ it might be as high as pH7. In alkali dermatitis readings up to pH12 were obtained. In these cases there appeared to be a deficient buffering capacity of the skin, as had been demonstrated by Prof. W. BURCKHARDT (Zürich) by his alkali neutralisation and alkali resistance tests. The buffering properties of the epidermis were attributable to the amphoteric properties of keratin, the diffusion of carbon dioxide, and the amino-acids of the skin secretions (Dr. D. J. H. VERMEER, Holland) and skin cells (Dr. H. SPIER, Munich). Increased alkalinity of the skin made it more susceptible to sensitisation, and according to Dr. M. SULZBERGER (New York) the pH might rise through undercleanliness, through overzealous use of detergents, and by infection. It was therefore a surprise that a victim of alkali dermatitis ever got better.

Dr. D. S. MITCHELL (Canada) described cases of wool dermatitis in Servicemen. One case of atopic dermatitis had been cured by using cotton and synthetic substitutes for woollen clothing: this patient's intradermal test with wool had been negative. Dr. J. H. TWISTON DAVIES (Chester) said he had seen no such cases since the end of the war, and that he felt there must be an endocrine factor in these patients, who were hypogonadal and had similar facies.

Sensitisation to chrome salts was found by Prof. H. Jaeger (Lausanne) to underlie many cases of cement dermatitis. Some cases of occupational eczema in pottery workers had been traced to sensitisation to cobalt (Dr. V. Pirilä, Helsinki). Polymorphic light sensitivity in cases of lymphogranuloma inguinale was described by Dr. C. E. Sonck (Helsinki). In his cases, no sulphonamides had been given. To their use Dr. D. Bloom (New York) ascribed three cases of bullosis mechanica toxica.

A.C.T.H. and Cortisone

Dr. L. A. Brunsting (Rochester, Minn.) said that the manner in which A.C.T.H. and cortisone acted in skin diseases was not yet known. It was certain that they did not alter the fundamental disease processes. He felt that their use was hardly justifiable in cases of chronic discoid lupus erythematosus. They could control the acute form of the disease, but remission depended upon continued administration. The milder cases of the acute form did not need cortisone but did well with rest in bed and blood-transfusions. The hormones do not abolish the "L.E. cell" phenomenon: indeed on necropsy, treated cases showed all the typical histological changes. An economical and effective way of giving cortisone was by intravenous drip using 500 ml. of 5% dextrose solution in 8–12 hours: in this way 10–20 mg. of cortisone was as effective as 100 mg. intramuscularly.

Dr. L. P. Ereaux (Montreal) found the hormones of use in the relief but not cure of pemphigus vulgaris. They were of less use in pemphigus vegetans, and cases of pemphigus foliaceus might be changed into rampant acute pemphigus. In spite of antibiotics, severe but masked infection remained a risk.

Dr. M. Sulzberger (New York) was more optimistic than other speakers. He thought that possibly pemphigus might be a self-limited disease if one could keep the patient alive long enough. He described the effect of the hormones on the allergic disorders as "morbidostatic": they did not inhibit the formation of antibody or its union with antigen. In some way they buffered the body against the effects of the reaction. Although the fundamental processes were unchanged, this was not entirely to the bad, since they did not alter the chances of a natural remission. The local application of cortisone was quite ineffective, even on denuded surfaces. The local use of Compound F, however, appeared promising.

According to Dr. D. Bloom (New York) the mouth lesions of pemphigus required much higher doses of the hormones than the skin—doses so high that side-effects are inevitable. Dr. B. A. Newman (California), unlike Dr. Sulzberger, had found it impossible to reduce the maintenance dose of the hormones in cases of atopic dermatitis: he also found topical cortisone specific for necrobiosis lipoidica and successful in chronic discoid lupus erythematosus.

Dr. R. Aron-Brunetière (Paris) found implants of 25–50 mg. of cortisone effective in Besnier's prurigo, dermatitis herpetiformis, and psoriasis. Dr. F. W. Jacobson (West Indies) described a case of generalised psoriasis which cleared up on traditional treatment only after cortisone was discontinued. Dr. C. Grupper (Paris) said that the pigmentation resulting from treatment with these hormones might be more ugly than the original dermatosis: it could be avoided by giving large doses of vitamin C and methionine during the treatment.

Tuberculosis of the Skin

The treatment of skin tuberculosis with calciferol was described independently by Dr. G. B. Dowling (London) and Dr. J. Charpy (Marseilles) during the war. Unfortunately the latter was unable to attend the congress and his paper was read by a deputy.

Dr. P. Marcussen (Copenhagen) indicated that there was a high rate of relapse in cases of lupus vulgaris treated with calciferol and that some of the old figures for Finsen light therapy were much better.

Dr. E. A. Sainz de Ajá (Madrid) said that despite the discovery of streptomycin, thiosemicarbazone, *p*-aminosalicylic acid, &c., there was still no drug which was to tuberculosis what arsphenamine was to syphilis. There was still a place for physical procedures—curettage, grafting, and cautery. Calciferol was of most use in lupus vulgaris. Thiosemicarbazones were of success in fistulised bone lesions, scrofuloderma, and Bazin's disease.

Preliminary treatment of cases of lupus vulgaris with P.A.S. and streptomycin permitted a shorter course of treatment with vitamin D_2, in the experience of Prof. M. L. O. Craps (Liége). Diamino-diphenyl-sulphone alone was ineffective in tuberculosis cutis (Dr. A. K. Banerjee, Calcutta). The action of calciferol on virulent and attenuated strains of tubercle bacilli had been studied by Dr. G. Wetherley-Mein (London). No inhibition of cultures had been observed after the addition of calciferol, the serum of calciferol-treated patients, or calcium. The healing of experimental wounds in guineapigs was not retarded by calciferol.

Lupus Erythematosus

Dr. Stephen Gold (London) regarded lupus erythematosus as a sensitivity reaction to various infections and drugs. In the chronic discoid form, the process was inhibited by the normally functioning pituitary-adrenal system. Where the latter was disturbed, the normal immune mechanism no longer operated and the disease became systemic. In the systemic form there was evidence of gamma-globulinæmia and antibody formation on an unusual scale resulting in cold agglutination, and a positive Coombs test and Wassermann reaction. Occasionally it was impossible to transfuse such patients, because of numerous abnormal antibodies. The L.E. cell phenomenon was not a constant finding. It was due to an immunologically distinct fraction of the gamma-globulin.

Dr. T. Inderbitzin (Zürich) described the artificial induction of the L.E. cell, using polymolecular anticoagulants—'Liquoid' (Roche), which is a sodium polyethanolsulphonate, and the sodium salts of polyvinyl alcohol sulphuric esters. He suggested that since these substances have physicochemical properties similar to heparin and hence chondroitin-sulphuric acid, the production of L.E. cells in acute lupus erythematosus may be due to the release of abnormal heparinoids from foci of collagen degeneration.

Psychiatry in Dermatology

Dr. Twiston Davies felt that a useful approach to the problem of psychiatric help for the skin patient was afforded by a scheme which he had operated for eighteen months. The psychiatrist sat in on almost all outpatient interviews, and was then able to select those cases which he felt could be helped by psychiatric means.

Dr. Ida Macalpine (London) had made a study of patients with facial dermatoses of various kinds. She had found no personality types in regular association with the skin diseases. In most there was a masked depression which had anteceded the rash. In cases of dermatitis of the lids there was evidence of suppressed grief. All showed paranoid concern with their appearance which was not found in cases of organic disease, such as lupus, in which the disfigurement was much greater. Improper handling of such cases might free them of their skin disorder but precipitate a thoroughgoing depression. Dr. Hugh Gordon (London) described the successful application of hypnosis to the treatment of itching dermatoses. Of his series of 102 cases, 51 were cured and 26 improved; 13 were still under treatment and there had been 10 failures.

Dr. J. Duverne (France) made a plea for objectivity in psychiatric investigation of skin cases. Dr. E. Hachez

(Westphalia) denied that this was possible, since "psychosomatics" was a point of view and nothing could be verified by amassing statistics. Dr. SULZBERGER said that he felt there was great likelihood of abuse of the psychosomatic approach: most non-dermatologists had greater difficulty with skin cases than any other, and to be able to attribute all and sundry lesions to "nerves" would obviate the necessity of precise dermatological diagnosis.

Dr. F. F. HELLIER (Leeds) felt that more could be achieved by dermatologists without psychiatric assistance if they were prepared to devote time to a sympathetic hearing of the patient's case with its social ramifications and economic burden.

Various Investigations

Dr. J. S. PEGUM (London) described estimations of the loss of protein by scaling and exudation in exfoliative dermatitis, psoriasis, and pemphigus. In some instances the serum-proteins were pathologically low, and the critical amount of loss appeared to be about 7 g. per square metre of skin per day. However, since psoriasis cases could lose as much and more without depression of the serum-proteins, it seemed likely that loss from the surface was not the sole cause of hypoproteinæmia.

Dr. T. B. FITZPATRICK (Rochester, Minn.) reported preliminary results of work which suggests that pigmented nævi contained an inhibited tyrosinase system, whereas malignant melanomata, whether pigmented or not, had an active tyrosinase system. This could be the basis of a test for malignancy.

Dr. C. J. WHITE (Chicago) reported histological findings in diseases of the nails. He described the occurrence of cocci in the nailplate suggesting that a bacterial onychitis must exist.

Special Articles

INGENUITY IN WHITECHAPEL

SOME recent developments in equipment at the London Hospital deserve to be generally known.

AN OXYGEN TENT

Work in cerebral, cardiac, and thoracic surgery has grown so much that oxygen tents are nowadays needed in quite large numbers: for patients prefer them, it seems, to B.L.B. masks, which are not comfortably tolerated after an hour or two. At the London there are often as many as a dozen oxygen tents in use at a time; and these, with their accessory cooling-chambers mounted on large metal stands, are costly to buy (£180–£237) and relatively expensive to hire. In any case it has been almost impossible to buy them at all lately, supplies are so scarce.

Fortunately the plastic canopies in which the patients are enclosed can easily be made, and Mr. R. W. Davis, instrument supervisor to the hospital, has found no particular difficulty in designing a home-made cooling-chamber and stand. In the original model, entry and exit ports were fitted to a 5-gallon drum, and this, with an escape pipe in the bottom, to allow water to run off, made an efficient cooler when filled with broken ice. The drum was lagged with an insulating jacket, and —with a bucket under it to take the water draining off the ice—was mounted on a wheeled metal stand. A right-angled arm, attached to the stand, carried the tent, which was fitted, by a collar, to the exit port of the drum, and slung to the arm by means of three metal bars like coat-hangers. The oxygen cylinder, of course, was connected to the entrance port. The upper part of the tent was made of transparent plastic, so that the patient could see and be seen.

This apparatus has proved to be thoroughly successful. Even the smallest nurse, when she wishes to put the whole apparatus away, can unhook the hangers, fold up her tent, like an Arab, and silently wheel off the stand. Moreover, the whole thing packs up against the wall in a very small space; even the carrying arm can be taken out of its slot, reversed, and put back, so that the long bar slips out of sight and only a short bar is visible.

The drum holds 20 lb. of ice, which needs renewing every 4–6 hours. Oxygen is run in at 10 litres per min. for the first 20 min. and after that at 6 litres per min. Tests made on volunteers showed that oxygen concentration reached 40% in 20 min. and 50% in 1 hour. The carbon dioxide level did not rise above 1·7% even after 4 hours of running with the canopy closed, and temperature and humidity remained constant during use. These results were almost identical with those obtained from the use of a standard oxygen tent.

Some 8 of these "London Hospital Pattern" tents have been in use in the hospital for the past year, with entirely satisfactory results, and they are now on the market at £50 apiece. The makers are Hospital Appliances Ltd., 18, Manor Road North, Hinchley Wood, Surrey.

STERILISING SYRINGES

Another good invention is a metal syringe-container for use in the hospital central sterilisation service. Before the war syringes were sterilised in the wards —as they still are in many hospitals. After the war they were centrally sterilised, parcelled up in grease-proof paper. This was quite satisfactory, but the packing took time, there were many breakages, and it was not always easy to get enough of the paper.

Mr. Davis has now devised cylindrical metal containers, made in four sizes, to carry syringes of different capacity. Any known make of syringe of the type which can be sterilised assembled will fit these containers. (At the London they use glass syringes with metal nozzles, the metal and glass being welded without the use of cement.) The flange at the base of the syringe rests on a circular constriction near the open end of the container; and the metal cylinder is narrower below this constriction, so that the syringe fits snugly down inside it with its needle pointing towards but, not reaching, the end of the tube. Part of the container above the constriction is cut away, so that the syringe can be slipped in without damage to the needle.

The cap which closes the container has a circular perforation in its side: when this lies opposite the place where the tube is cut away, steam can enter through it during autoclaving. After sterilisation the container is closed by turning the cap so that the hole no longer lies opposite the open part. It can then be dated with an ordinary date stamp and sealed with a strip of 'Sellotape.' A piece of non-absorbent wool in the cap acts as a filter for dust and protects the syringe against mechanical damage: even when the container is thrown violently on the floor, the syringe generally remains intact. Breakages, which with the old paper pack amounted to 1 in 160 syringes sterilised, have now fallen to 1 in 550. Moreover much time and space have been saved: at the London they sterilise 3000 containers a week, and one man using a 6 ft. bench for packing can pack, sterilise, date, and seal 60 containers in an hour.

The containers cost 3s. each (which is less than must be paid for a heat-proof glass container of the same size) and they last more or less for ever. Tests have proved that their contents remain sterile after autoclaving or hot-air sterilisation. The point of the needle cannot be damaged whether the nozzle is of the central or the eccentric type; and if the needle is firmly fitted in the first place it does not come off. In the wards, of course, it is a great convenience to be able to use the syringe straight away without having to assemble it.

The containers, like the oxygen tents, are made by Hospital Appliances Ltd.

RADIO-OPAQUE SWABS

The London Hospital has recently taken to using, as a routine, swabs with a thread which is opaque to X rays woven into them. In any uncertainty about the swab-count, the patient is now radiographed at once, and any question of a swab being retained is settled out of hand. Several brands of these swabs are on the market, but some are said to be unsatisfactory, because, though they are opaque to X rays outside the body, they do not throw a detectable shadow through the tissues of the patient. 'Ray-Tek' swabs, the brand used at the London, are made in England by the American firm, Messrs. Johnson & Johnson of Slough. Only one criticism is offered against them—that they are made only in small sizes. Large swabs, measuring 9 × 6 and 10 × 9 in. are now in use in operating-theatres, and it is not so difficult as might be supposed to pack one of these into the abdomen and overlook it. Devices for preventing such accidents are never foolproof. It is easy enough to clip a Spencer Wells forceps on to each swab as it is put in position; but it is natural, and equally easy, in case of sudden hæmorrhage, to seize the nearest forceps to control it, and let the released swab take its chance. A system which ensures that, in case of a miscount, no swabs will be left in the patient, is a safeguard on which every surgeon (not to mention every patient) should be able to depend. A general demand for these swabs seems likely, and manufacturers might well turn their attention to providing them in the large sizes now so commonly used, as well as in smaller sizes.

SILENT CURTAIN RUNNERS

To be roused from sleep by the abrupt clash of curtain runners can be quite an alarming experience, even for those who are perfectly well. Every bed at the London, now, can be enclosed in a cubicle of curtains, to the great comfort and satisfaction of patients. But when these are drawn, the familiar rattle is absent. The little wheels travelling along the grooved bar, with which we are all familiar, have been replaced by strips of metal, covered in strong woven cotton, and bent to grip the bar at each side. These slide as readily as wheels, but with a gentle and soothing susurrus, hardly to be heard. They are made by Messrs. Cope & Timmins, 91 and 93, Paul Street, Finsbury, London, E.C.2.

The Wider World

IN EASTERN NEPAL

MICHAEL WARD

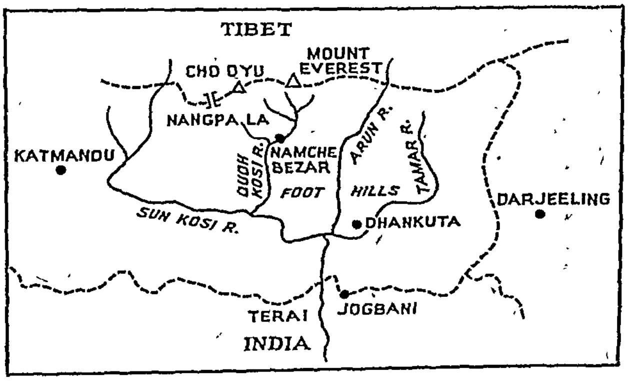
M.B. Camb.

WHEN the 1951 expedition explored Mount Everest from the south, few doctors had been through Eastern Nepal. I knew of an American doctor who had travelled in this area but of no others. I had no microscope or other aid to diagnosis, except a stethoscope; and to talk to the local inhabitants I needed one and sometimes two interpreters.

We started on the edge of the *terai*—the jungle-covered plain—at a town called Jogbani (see sketch map). A good many people here were pock-marked, and cholera epidemics broke out fairly regularly. *Aul* or malignant tertian malaria was prevalent in the *terai*, especially in the monsoon season. The number of cases usually began to decrease by the end of September. Chronic diarrhœa —presumably a chronic dysentery—was endemic, but no-one took any notice of it. I saw a few people with scars in the groin—possibly the result of lymphogranuloma inguinale.

Our party then spent three weeks in the foothills, at heights varying from 1500 to 8000 feet. Sanitation in the villages was non-existent: the streams which supplied drinking-water were invariably used as lavatories as well; and villages could be smelt long before they were seen. The houses abounded with insects of different kinds; and our sleeping-bags often became infested with insects from those in which we stayed. D.D.T. was very useful but we did not have enough of it.

Dhankuta, the main village of the area, had cholera and smallpox, but its height of 5000 feet meant that there was little if any malaria. We crossed the River Arun, at 1500 feet, soon after leaving Dhankuta. The Arun valley has a bad name for malaria. We travelled along its banks for two or three days, and saw a few people with "fever." We came across many leeches, especially on the paths near the villages, and the animals belonging to the villagers were covered with them. The natives picked them off with their fingers—they seemed to have no other way of dealing with them—but when we did this we developed sores which did not heal until the monsoon stopped.



We passed a village which had been attacked by a "plague." People were dying after four or five days' illness with a high fever. There were no swellings on their bodies, no eruption or rash, and no diarrhœa. In this area similar epidemics broke out from year to year in the monsoon period in one or other of neighbouring villages, separated from each other by deep gorges. I thought the disease might be typhus, but, as all my information was second-hand from different interpreters, it was difficult to tell. Near this village our party lost their way along one of the paths, which were very bad, and inadvertently walked through a hornets' nest. A few porters were stung 4 or 5 times; within fifteen minutes they began shivering violently and sweating. I had no thermometer immediately handy, but their pulse-rates were between 120 and 130. Within six hours they had recovered, though they all thought they were going to die.

We arrived at Namche Bezar (12,000 feet) in the third week of September at the end of the monsoon. I saw several people with gonorrhœa; in some cases the infection was several weeks old. They said they had contracted it in Tibet, a few miles away over the Nangpala pass (19,000 feet), but I think it was also present in Namche Bezar. During the exploration of the southern approaches to Everest we returned to Namche Bezar several times. Once a member of the party ate some local honey, and lost consciousness for about ten minutes. Apparently Nepalese honey is poisonous in October and November because the bees then feed on rhododendrons.

I heard of another epidemic in the valley of the Dudh Kosi, 2000 feet below Namche Bezar. It started after the monsoon, and attacked the villages along the river. Abdominal pain and nose-bleeding were common symptoms. This may have been one of the acute epidemic hæmorrhagic fevers, akin to the one which has been encountered in Korea.[1]

Blepharitis, chronic conjunctivitis, and cataracts were fairly common, especially in the Namche Bezar region.

Our party suffered less from sore throats and respiratory infections than those who approached the mountain from the north. The moister atmosphere was probably responsible; we had less dust and wind to contend with than in Tibet, and previous expeditions had not had the advantage of antibiotics. All of us, including the Sherpa porters, took proguanil ('Paludrine') while we were in the malarial areas, and for three or four weeks after we had left them. None of the party suffered from malaria; the risk was not great because we crossed the *terai* rapidly in a lorry, and we were not in the worst areas for long.

Medicine and the Law

The Straffen Case

IN October, 1951, John Thomas Straffen, charged at Taunton assizes with the murder of a child, was found unfit to plead and was ordered to be detained "until His Majesty's pleasure be known"—the direction of indefinite duration usual with persons sent to Broadmoor. On July 25, 1952, Straffen, charged at Winchester assizes with the murder of another child, having pleaded "not guilty," was found "guilty" and was sentenced to death. As his counsel observed in his final address to the jury, the medical evidence offered by the prosecution and by the defence was unusually harmonious. The witnesses substantially agreed that he knew, when he killed the child, that he was doing wrong; the difference between them was that the Crown witnesses said he knew perfectly well, while the defence witnesses said he knew, but only within the limits of his limited intelligence. The defence was in the difficulty, not infrequent in such cases, of contending firstly that Straffen was not the man who killed the child, and, simultaneously or alternately, that, though he might have killed her, he was not responsible for his actions. It is hard to assert the first plea convincingly if the main battle develops on the second.

The Solicitor-General, who prosecuted, obtained the leave of the court to offer evidence of the similar killing of two other little girls attributed to Straffen. This course, prejudicial to his chances of acquittal, was permitted as in the interests of justice because, although helping to establish the identity of the killer, it was capable of proving the design or criminal intent in circumstances of remarkable similarity. As usual, the jury had to be warned that they were trying Straffen upon the charge of one killing only. Normally the law is particularly careful to exclude evidence of previous similar offences by an accused person; a jury must not be asked to conclude that, because he has previously committed similar crimes, it is probable that he has committed the crime with which he is charged, although juries would really be more than human if they managed to keep out of their minds such an element of strong probability as would certainly influence them in the ordinary affairs of life.

A police officer's evidence of Straffen's history, elicited more fully in cross-examination by Straffen's counsel, was as follows.

> Born in 1930, he went with his mother to India (where his father was a serving soldier) at the age of 2. Brought back to Bath in 1938 with his family, he attended school up to the age of 10, when he was certified as a mental defective under the Education Act. In 1939 he was charged at the Bath juvenile court with larceny of a purse from a little girl and was placed on probation for two years. Seven months later he came before the Bath magistrates for breach of the terms of probation, was certified as a mental defective, and was sent to a home for defectives. From an institution of this kind (to which he had been transferred) he was discharged in 1946, having reached the age of 16. Returning to Bath, he worked as an errand-boy.
>
> Next year he was arrested on a charge of housebreaking. When tried at Bath quarter sessions, he asked for one other charge of housebreaking and 11 charges of larceny to be taken into account. The police then informed the court that Straffen had wrung the necks of five fowls, leaving their carcases in the fowlhouse, had assaulted a 13-year-old girl, and had said—though no proof was forthcoming—that he had committed several sexual offences. He was certified a mental defective for the second time and removed to an institution for mental defectives from which he twice escaped. He was granted a licence in April, 1951, and went back to his parents in Bath, working in a market garden.
>
> Brenda Goddard, aged 6, was murdered in Bath by strangulation in the following July. Five days after Straffen had been seen by the police, Cicely Batstone, aged 9, was similarly murdered. Tried at Taunton assizes in October, he was (as already stated) found unfit to plead, the only witness being Dr. P. W. J. Parkes, medical officer at Bristol prison. Straffen escaped from Broadmoor on April 29 last. Linda Bowyer, aged 5, was similarly murdered later on that day, not far away.

Dr. C. R. Gibson, the Bath police surgeon, gave evidence of the manner of death of Brenda Goddard and Cicely Batstone. Dr. R. D. Teare, the pathologist who examined the body of Linda Bowyer, indicated the similarities discoverable in all three cases. There was no sexual interference or other injury than strangulation in any of them. Of the medical witnesses for the defence Dr. A. Leitch said he had first seen Straffen in 1947 when in the prison service at Bristol. Straffen was a feeble-minded mental defective with little or no moral sense. Dr. Leitch thought he felt no more emotion in killing these girls than a normal person would feel in killing a fly. He showed no regret or remorse, but rather took pleasure and pride in speaking of his delinquent actions; his mental age was 9½ years. He saw him again in Bristol in 1951; an encephalograph indicated abnormal functioning of the brain. Straffen was unable to foresee the real nature and consequence of his acts: he told the witness that he killed Cicely Batstone to annoy the police, and that it was a sensible thing to do and easier than stealing; after the crime he slept soundly. He had seen Straffen at Wandsworth prison in the present month; the mental condition showed only slight changes; he had become more familiar in a glib way with court procedure, but his intelligence and reasoning power were no better; he was rightly certified as a mental defective; his condition was incurable. He knew the nature and quality of his acts, but only within the narrow limits of his own defective low intelligence; from the medical point of view he was not insane. Mr. Justice Cassels put some significant questions to the witness:

> Q. Do you think he has a desire to kill?—A. His desire to kill seems to me to spread from his desire to pay back the police because of his hatred of them.
>
> Q. Had he the intelligence not to select a policeman to strangle but a defenceless girl?—A. Evidently, my lord.
>
> Q. You say he knew the nature and quality of his act within the limitations of his intelligence and he knew he was squeezing a human throat; did he know he was squeezing a little girl's throat?—A. Yes.

Dr. Parkes, recalling that at Taunton in October he had told the court that Straffen was unfit to plead, said he was now fit to plead; the accused had profited by his experiences. Dr. R. S. Williams said Straffen came under his personal care at Broadmoor from last November till his escape; he was a feeble-minded person; he knew the nature and quality of the act of killing Linda Bowyer but not as a normal person.

Although it may have been doubtful how far this medical testimony would affect the verdict, the Solicitor-General obtained leave to call rebutting evidence. Dr. J. C. Matheson, principal medical officer at Brixton prison, said that Straffen gave him a clear account of his movements after his escape from Broadmoor; he needed little prompting and was able to trace his route on a map. He was feeble-minded and certifiable as such, but not insane; he knew that, if one killed a person, one should be punished; he was simple and childish in conversation. Dr. J. H. Murdoch, principal medical officer at Wandsworth prison, said Straffen showed no signs of insanity while there. He would put him in a higher category than feeble-minded; he was rational in conversation, well behaved, clean, and tidy; Straffen said he had played contract bridge in Broadmoor; he knew how many cards and suits there were in a pack. He was sane. "Sane although he has been in Broadmoor?" asked counsel for the defence. "Yes," replied the witness, "there are quite a number of sane people in Broadmoor." Dr. T. A. H. Munro, physician in psychological medicine at Guy's Hospital, said that Straffen was feeble-minded, "of a high-grade type, coming at the top end of the scale"; he was unstable.

These expressions of opinion will be important if, as is usual with all convictions of murder, the verdict is to be examined in the Court of Criminal Appeal. The Rules in McNaughten's case appear to be inapplicable. The facts may stir the public conscience, but the public may show less interest in forensic disquisitions than in the problem of what to do with persons who have Straffen's history.

Public Health

Poliomyelitis

POLIOMYELITIS notifications in the week ended July 19 were (previous week in parentheses): paralytic, 104 (78); non-paralytic, 59 (41); total, 163 (119).

A comparison between this year and the preceding five years is as follows:

Year	*Total cases up to and including 29th week*	*Cases in 29th week*
1947	805	193
1948	791	45
1949	847	99
1950	1920	261
1951	1161	134
1952	1176	163

Up to and including the week ended July 19 the overall notification-rate for England and Wales was 2·68 per 100,000 population.

The districts which have notified 10 or more cases up to July 19, with incidence per 100,000 population, are:

District or borough	*Total cases*	*Incidence*
Gateshead	61	55·2
Felling	21	83·3
Liverpool	23	2·9
Woolwich	17	11·3
Newcastle upon Tyne	32	11·0
Birmingham	41	3·7
Leeds	36	7·2
Manchester	23	3·3
Whickham	13	61·0
Ealing	10	5·3
Harrow	13	5·9
Blyth (Suffolk)	12	46·1
Coventry	10	3·8
Malvern	10	51·0
Sheffield	13	2·5
Cardiff	14	5·7
Yeovil	18	102·0

The increase in weekly notifications is maintained, and the disease is becoming increasingly distributed throughout England and Wales.

Statistics for the Second Quarter

The Registrar-General[1] announces the following provisional figures for England and Wales in the quarter ended June 30 this year (corresponding figures for the same quarter last year in parentheses): birth-rate 16·0 (16·6) per 1000 population; stillbirth-rate 22·4 (22·5) per 1000 total live and still births; death-rate 10·6 (11·1) per 1000 population; and infant mortality 25·1 (28·7) per 1000 related live births.

In England Now

A Running Commentary by Peripatetic Correspondents

WHAT is the quaintest oddity on permanent view in the streets of London? I have been abroad over-long and perhaps the competition has already been held. If not, I would confidently enter No. 429, The Strand. In Muirhead Little's history of the British Medical Association up to 1932 is described the installation of the Epstein statues on the outside of the old B.M.A. building, showing "physiological and pathological changes in the human form." The author describes a "stunt" by an evening paper castigating the "outrages upon decency and good taste." He continues: "the statues have since been allowed to rest in peace, scarcely noticed by the passer-by, in their elevated position." I ask you, *have* they? After a diet of mutilated Dissolution statues in provincial cathedrals and abbeys—even the painful climbers up Jacob's 40-feet stone ladder on the west front of Bath Abbey were beheaded—I returned to London and went to enjoy those Epstein statues. But it looks as though some mighty-muscled mason has rioted in an orgy of weird operative surgery—amputation, decerebration, thoracoplasty, mastectomy, infanticide, and steatopygectomy. Eighteen dejected remnants keep their vigil high up there, and proclaim that London's outraged philistines are more easily pacified than London's atmosphere and weather.

* * *

Our new neighbours have just moved in, and their first care was to erect an H above their chimney. Thanks to the B.B.C. report on television this has saved us an immense amount of trouble. Thumbing our copy of the report we deduced at once that we are not likely to be asked to act as half of a bridge four or as "sitters-in," that our neighbours have not read any good books lately, and that their income is less than £650. Most comforting of all, we find that their educational level is lower than our own. *We* have a radiogram.

* * *

A scientific friend of ours had occasion recently to attend a meeting in one of the brisk industrial cities of the North, and was offered accommodation in a women's hostel. Ever anxious to see how the other half lives, our friend accepted; and it is a tribute to his scientific spirit that he persevered even on finding that the female denizens were still in residence.

He was a trifle mystified to find in his room a notice saying "No furniture is to be removed from this room without permission of the warden," but it came to him that the midnight-feast tradition of his own schooldays might be represented among the female sex by midnight furniture-removing parties. The hormones, you know. He was, however, fascinated to find similar notices on the top of the bookcase and on the back of the wardrobe. The room was dark and damp, and surrounded on all sides by a stand of sturdy rhubarb. However, the high holiday spirits common to all whose expenses have been paid carried him through until bedtime, when he first took adequate stock of the sleeping apparatus provided.

Our friend is a large man, and like so many large men nowadays (and for that matter small women too) he suffers from a Disc. The bed had been designed for an achondroplasic some four feet in length, and a large iron bar had been placed at either end to prevent the achondroplasic from pushing her feet or her head beyond the allotted span. It was now too late to make representations, and there was nothing for it but to sleep on the floor. The bedding came off reluctantly, exposing a by now familiar notice on the bedstead.

Our friend spent an uneasy night. The stairs re-echoed to the sound of girlish laughter until after midnight, and in a room across the rhubarb a furniture-removing party was in progress. He was able to stem the torrents of light and sound flowing through the fanlight with a blanket, and, flushed with success, attempted a similar operation on the window, a pane of which promptly fell out with a thunderous crash into the rhubarb. Our friend waited timorously for the Head Girl, but no-one took any notice; clearly windows did not come under the furniture-removing ban.

---

[1] Registrar-General's Return for the Week ended July 19. H.M. Stationery Office. Pp. 20. 1s.

At two the owls took over, rooting mournfully about in the rhubarb outside the space where the window had been. Our friend is something of an ornithologist, and recognised every known British species as well as a number of South American families. The floor was hard, and so were the osteophytes in his lumbar spine. Moreover, there were several pieces of scrap metal in his pillow, and at half past four he gave it up and concentrated on his Simenon.

There were no mirrors in the bathroom—so much for feminine vanity—and our friend shaved guiltily by his reflection in the door-knob, not daring to remove the mirror from his room without first approaching the warden. After breakfast he left as hurriedly as possible, having first signed himself in on the visitors' book as a male guest of the Head Girl on the previous evening and carefully omitted to sign himself out again.

* * *

Holland is still one of the most charming countries in Europe, and Dutch hospitality is as warm as ever; but I do wish they did not keep such a virulent brand of mosquitoes. Perhaps it was the admirably hot spell of weather which was produced for the International Diabetic Conference the other week, or perhaps I am becoming "allergic" to the little brutes, but I have never been so effectively bitten night after night. The next time I go I shall certainly not forget to take an ample supply of dimethylphthallate; or perhaps the Dutch authorities will remedy the situation by supplying all hotels with quantities of D.D.T. It is an interesting commentary on the progress which has been achieved in public health that one should have been more worried by mosquitoes in Western Europe than in Malaya—but such at least has been my experience.

* * *

> "In discussing the results of treatment we must bear in mind that all, or almost all, the reported cases have been of one type, viz., patients suffering from very advanced disease, in whom other methods had proved incapable of arresting the morbid process, and in whom the mortality would most likely have been at least 90 per cent. Many cases have been too recently published for us to be able to judge what their ultimate fate may be, but undoubtedly the initial results have been full of promise. Certainly well over one hundred cases have, however, been recorded . . . and in these there would seem to have been a permanent arrest of the disease in at least 60 per cent. In many of the more recent cases immense improvement has already ensued, and patients who a few months back seemed almost moribund now appear to be on the high road to recovery."

Isoniazid? No, Mr. Hubert Chitty on the "Artificial Production of Pneumothorax in Phthisis by Injection of Nitrogen" in the *Bristol Medico-Chirurgical Journal* for 1912.

* * *

It is useless (they said) to go down to the River until we get some rain. The River is so low (they said) as to be almost stagnant. If you fish it in its present condition (they said), you will be wasting your time. Fortified by all this good advice I went down to the River. It was a lovely evening, hot and thundery, and the River was exactly as they said it would be, a thin trickle, glassy still, and clear as gin. A few fingerlings were rising at something so small as to be invisible and the midges were active. Conscientiously I fished up the whole length of Top Meadow. One or two tiny trout played leapfrog over my cast but did not take hold of my fly. This year's brood of mallard flew over my head within easy gunshot, and a dipper, flying straight and purposefully, passed to and fro. My spaniel swam lazily across the River several times, crossing just in front of my line, which did not improve my chances, and by 9.15 P.M. I had accomplished nothing. I went down once more to the bottom of the water and fished up Head Run. About twenty yards from the top I caught a fat dace which fought surprisingly well. This was better than nothing. Two casts later I was smartly taken by a peal, which came out of the water half a dozen times. Handling him roughly I dragged him downstream, and, having no net, chased him out on to a patch of shingle. He was a pretty little fish of rather more than a pound and in excellent condition. It was nice to feel that, despite what they said, I had not wasted my time.

Letters to the Editor

HOSPITAL BEDS FOR MENTAL DEFECTIVES

SIR,—It is refreshing to see that an increasing interest is being taken in this problem, though even now the whole truth has yet to be stated. The figures given in Parliament by the Minister of Health, and quoted in your issue of July 19, still fail to give a complete picture of the appalling state of affairs. It is generally accepted that 2 per 1000 of the population—i.e., 100,420 people—need hospital care by reason of their mental defectiveness. If only 48,742 patients are occupying beds, as given in the Minister's figures, then there should be 51,678 on the waiting-list, not a mere 8070. The fact is that waiting-lists have long since ceased to have any meaning because ascertainment, having become futile, has often been neglected. If waiting-lists were complete and the present admission-rate remained unchanged, it seems that a patient ascertained today would have to wait some 15 years for a vacancy. Unless these facts are faced, the magnitude of the problem will not be realised and it will only be met by half-measures.

If the national conscience is not stirred by the thought of more than 50,000 inarticulate persons in need of care and treatment, and of the distress caused to their relatives, then we have indeed reached a sorry plight.

Morpeth, Northumberland. C. GUY MILLMAN.

THE McNAUGHTEN RULES AGAIN

SIR,—The recent discussion of the McNaughten Rules in your columns raises once again the question as to wherein their inadequacy lies.

Dr. Haas and Mr. Ellison (June 21) argue the absurdity of the Rules, reasoning from presuppositions implied in their crucial points which bear on the questions designed for the jury. "In order," they conclude, "to determine whether a man is insane, so as not to be responsible in law for his acts, one assumes that he is a reasonable man."

Part of this conclusion is certainly valid in a sense which will emerge later. In its entirety, however, it would seem rather to obscure the issue, which is precisely that the McNaughten Rules are not primarily designed to determine whether a man or woman is insane—i.e., suffering from a psychosis. If they were so designed no judge would presume to rule, unaided, whether an issue of insanity should go to the jury. He would leave the diagnosis of psychosis to an expert, preferably to an independent panel of experts. But we know that, even when established, psychosis per se does not exempt an accused person from criminal responsibility.

This is what many psychiatrists feel to be the inadequacy of the legal practice. "Insanity" has, after many centuries, at last acquired its due status as a natural illness—not the only one, one should remember, that may be killing to others—and the psychiatrist, to paraphrase John Haslam,[1] objects to his patient receiving his cure at the gallows.

The whole vexed problem might perhaps be brought a step nearer solution if attention were given to the attitude of the authors of the legal doctrine towards insanity. Mr. Justice McCardie is quoted[2] as having said that insanity was one thing from the medical point of view and another from the viewpoint of criminal law. How does the criminal law view insanity?

The relevant legal thinking is given in the reply of the judges to the fourth of the questions put to them at the historic session of the House of Lords. The question reads: "If a person under an insane delusion as to existing facts commits an offence in consequence thereof, is he thereby

---

1. Medical Jurisprudence. London, 1817; p. 4.
2. See Henderson, D. K., Gillespie, R. D. Textbook of Psychiatry. London, 1947; p. 694.

excused ?" The judges replied[3] that a great deal depended on the nature of the delusion. If, under the influence of his delusion, the accused had supposed another man to be in the act of attempting to take his life, and he killed that man, as he supposed in self-defence, he would be exempt from punishment. If his delusion was that the deceased had inflicted a serious injury to his character and fortune, and he killed him in revenge for such supposed injury, he would be liable to punishment.

It will be noted that although the *question* refers to "an insane delusion as to existing facts," the *answer* transposes facts belonging to the plane of mental pathology to the plane of objective reality with the result that the psychotic act is regarded as if it had arisen in an objectively real setting.

In this sense one has to agree with Dr. Haas and Mr. Ellison. The psychotic *is* being treated as if he were "a reasonable man"—that is to say, any man of sound mind who, as in the examples cited, has met with a real threat to his life or with a real injury of a lesser kind and has acted either within the law or by breaking it. Thus criminal law views insanity by looking, as it were, the other way, *by denying it*. In so doing it mirrors an age-long attitude of society towards mental illness.

In the very circumstance of this denial of insanity and in the consequent dealing with the psychotic on a basis of equality with the mentally healthy may perhaps be sought the psychological source of the contentment with which the judiciary appears to regard the McNaughten Rules. The lawyer may, in a vague manner, feel proud of the advance which lies in the fact that the psychotic is treated on a level with his mentally healthy brethren and not worse—as, an outlaw for centuries, he used to be treated.

In writings from periods of transition one meets with a curious co-existence and conglomeration of new insights and outworn attitudes. The McNaughten Rules are in this category. As such they inherently fail to do justice to modern demands.

West Park Hospital,
Epsom.

J. ZELMANOWITS.

FLUORIDATION OF WATER-SUPPLIES

SIR,—The U.S. Select Committee on Chemicals in Food issued their findings on fluoridation of water-supplies on July 10. They warned against precipitate action in the use of what is still a relatively new means of reducing dental decay, and recommended caution in adding fluorides to drinking-water. They pointed out that there are a number of "unanswered questions" and that a conservative attitude is warranted. They urged that all the facts about fluoridation be made public in communities where its use is under consideration, and that the people in each community be given the opportunity to decide whether they wish to take what is at this time still "the calculated risk" inherent in fluoridation programmes. They chided the fluoride supporters who say, that the use of fluorides is comparable to the long accepted practice of adding chlorine to drinking-water, for chlorine is added to destroy harmful bacteria while fluoridation causes "a physiological change in the body."

Lieut.-Colonel E. F. W. Mackenzie, in his recent paper,[4] claims to have given the pros and cons, and he makes out a strong case for fluoridation. He omits to state however that, where water containing 1 part per million of fluorides is in use, as many as 10% of the children may have varying degrees of "mottled teeth." He does not mention that, where cryolite has been used on fruit crops, an apple can contain as much as 1 mg. of fluorine (the approximate amount in four glasses of water containing 1 p.p.m. of fluorine). He states that the use of high-fluorine waters for irrigation did not increase the fluorine content of vegetables, but contrary evidence was given before the committee by Mr. H. V. Smith, associate agricultural chemist of Arizona University.

The basic ethical objection to compulsory mass medication is reinforced by the committee's adverse findings. Would it not be a good idea to explore more fully other methods of adding fluorine to the diet of those who need and want it ? In 1950 Prof. W. A. Albrecht, of the University of Missouri, wrote an important paper on the Pattern of Caries in relation to the Pattern of Soil Fertility in the U.S.A., in which he suggested that "the soil fertility pattern, not in terms of higher yields but of quality output, deserves more consideration in looking at the health condition of the teeth."

LIVER EXTRACT FOR HERPETIC PAIN

SIR,—Professor Dunlop is reported in your issue of July 19 to have said at the Dublin meeting of the British Medical Association that the injection of liver extract is of no value for the relief of pain in herpes.

In the last year I have treated 4 such cases.

In 3 of them the pain disappeared in twenty-four hours, never to return. In the 4th the pain, which was agonising and involved the area supplied by the left brachial plexus, disappeared, but was succeeded by intense itching. In each case 'Campolon' 2 ml. was injected intramuscularly, and it seemed to me that the change of infliction in the last case might be due to an insufficient amount of some constituent in the liver extract.

I therefore quite empirically gave an injection of vitamin B_{12} ('Cytamen' 2 ml.) and the itching vanished overnight. When I last saw the patient a week ago he had been free from symptoms, except slight numbness, for a month.

Being a clinician and not a chemist I cannot explain things of this nature, but I shall continue to use liver extract until and unless I am convinced that my experience is entirely fortuitous. There are times in general medicine when the aphorism of Pascal, that the heart has its reasons which the brain cannot understand, seems evident; and as the relief of pain without the unnecessary use of narcotics is in all our hearts I hope that this simple procedure will be given an extended trial.

London, W.1.

CHRISTOPHER HOWARD.

PROVISION FOR THE MENTALLY DEFECTIVE

SIR,—The differences between Dr. Rose and me are, I think, more apparent than real, and have arisen from the necessity for brevity in writing. To reply point by point :

1. The fact that intelligence is distributed amongst the population in a continuous curve is generally accepted, and I did not think it necessary to refer to it.

2. That the justification for making distinctions between different groups is an administrative one is also agreed, but the distinctions are supported by laws and regulations which are for the specific purpose of providing the most suitable environment for the individual concerned. It follows that there will be, at the merging of the groups, borderline cases, and the decision how they can best be placed may prove difficult and require a period of observation.

3. Dr. Rose feels shocked at the expression "stigma of mental defect" and says it does not exist except in the minds of the ignorant and prejudiced. He admits, however, that it does actually exist, and to call those parents who feel it "ignorant and prejudiced" may be true but does not really solve anything. One still has to endeavour to get the parents' confidence and fullest coöperation. That the stigma ought not to exist is true, but the same would apply to that sometimes attached to many other mental and physical conditions.

4. To suggest that we are perpetuating ignorant prejudices by assuring some anxious parents of educationally subnormal children, in reply to their queries, that the special

---

[3] *Ibid*, p. 692.
[4] *Lancet*, 1952, i, 961.

schools are not for mental defectives, is very strange indeed. We are merely telling the truth and it is a truth that needs telling as it is not sufficiently widely known.

5. As Dr. Rose is concerned that we are not helping to educate public opinion in an enlightened attitude towards mental deficiency, I can reassure him. My letter did not deal with this, but on meeting children who are ineducable and telling their parents that they will require to be notified under the Education Act, 1944, Section 57/3, some parents may show, in addition to intense disappointment, personal shame and hurt pride. It surely goes without saying that we do all that we can to help them to develop a healthier attitude to their problems.

Sheffield. M. C. TAYLOR
School Medical Officer.

PERIODIC DISORDERS OF CHILDREN

SIR,—In your issue of July 12, Dr. Howells rightly welcomes Dr. White Franklin's article (June 28) on periodic disorders of children. We agree with Dr. Howells when he implies a greater place for psychiatric help in managing these than did Dr. White Franklin; but we disagree with Dr. Howells's statements (1) that "explanation is futile," and (2) that "it is clear that the . . . psychiatrist should . . . apply the psychotherapy."

Simple exploration and psychotherapy (including explanation) by a family doctor or a pædiatrician does, in some cases, bring about a cure and not merely symptomatic improvement. Perhaps the pædiatrician will try to treat some unsuitable cases and thus delay their arrival at a psychiatrist's clinic, but it would be impracticable for a pædiatrician to send to the psychiatrist all the children he sees with symptoms of emotional origin; already at many psychiatric clinics the interval before a patient's treatment starts is months or years. Is the general practitioner or pædiatrician to refrain from treatment?

Part of the function of a *consultant* (perhaps he may be contrasted with a *specialist*) is to teach the doctor who sends or brings cases to him. It seems to us important for the family doctor and pædiatrician to learn which are the most suitable cases to be referred to the psychiatrist. On occasion it is reasonable for a pædiatrician to get help in *diagnosis* from the child-guidance clinic and then himself, for a time at any rate, do psychotherapy.

Child[illegible] CHRISTOPHER HAFFNER
Chi[illegible]
Guy's [illegible] RONALD MAC KEITH.

SIR,—The problem of the child so emotionally disturbed as to need a visit to the doctor is one of practical concern to the assistant medical officer working in the local-authority service, the general practitioner, and the pædiatrician.

The recognition of a psychiatric disorder is important, but Dr. Howells is being unrealistic when he suggests that "the child psychiatrist, or, better, family psychiatrist, should explore the psychopathology and apply the psychotherapy." The frequency of the condition, which some have put as high as 50% of all children's illness, and the disturbing effect on the child, the home, and the school necessitate action more immediate than is possible with the very long waiting-lists of the child-guidance clinics. Confronted by these disturbed children in clinics, surgeries, and outpatient departments, a sympathetic attitude combined with the will to treat can go a long way in helping parents in the understanding of the emotional needs of their child. It is encouraging to see parents becoming aware, so often for the first time, of what has been wrong and the almost immediate effect this has on both parent and child. This understanding differs fundamentally from "the explanation—the mere instruction—the mechanical change of technique" which Dr. Howells puts as the only alternative to full-blown psychotherapy.

In answer to the needs of the patient we must do what we can, and in the process of so doing acquire more skill, experience, and judgment. It is time, however, that psychiatrists made some efforts to bring their special knowledge to doctors working with children in order that they may be better equipped in their work in this field.

London, N.W.3. DAVID MORRIS.

CAR-DRIVERS WITH DEFECTIVE VISION

SIR,—The statement (July 19) of the Faculty of Ophthalmologists on the danger of visual disabilities in people driving motor vehicles is of great interest to members of this association, emphasising as it does the weakness in the present system of issuing driving licences.

This association thinks that the fact that a candidate for a driving test wears spectacles should be recorded on the driving licence. This would ensure that, in the event of such a driver being involved in an accident, it would be possible to check whether or not he, or she, was wearing spectacles at the time, or, in other words, was properly equipped to be in charge of a vehicle.

One of our members has reported that in the past year he has handled two cases in which elderly people, after being involved in accidents, were convicted of dangerous driving and had their licences suspended until they passed a driving test. In *both* cases, the instructor detected signs of defective vision immediately. On his advice they consulted ophthalmologists who advised them both to give up driving. Fortunately, in these cases this advice was taken.

We know of another candidate who failed the test because of defective vision. After the test she admitted to her instructor that she knew that she had bad eyesight, but said that she did not like to wear spectacles. She did, however, get spectacles, entered for the test a month later, passed (with spectacles), and has not worn them since.

London, N.W.3. The Motor Schools Association.

HALLUX VALGUS

SIR,—While welcoming the authoritative survey by Dr. Hardy and Mr. Clapham (June 14), I am not entirely happy about the radiographic technique employed in collecting the data.

With the technique used, the distortion produced will tend to show a metatarsus varus, by virtue of the divergence of the cone of X rays centred, as it was, between the two feet. Furthermore, owing to the lateral direction of the projection of each foot, as the angle between the first metatarsal and the plane of the film increases, so an increase in the apparent degree of hallux valgus will be seen in the radiograph. Moreover, as the centre of the cone of rays was not directed through the apex of the angle formed by the first and second metatarsals, the angle of the first interspace would be apparently narrowed; and as the dihedral angle between the plane of the first and second metatarsals and the plane of the film increases, so the angle between these two bones in the radiograph will apparently decrease.

The type, then, with the higher longitudinal arch will tend to show in the radiograph, taken under these conditions, a greater degree of apparent hallux valgus together with a narrowing of the first interspace. Is this not significant in view of the findings of the survey?

Having spent some thirteen years in radiography before turning my attention to the foot, I remain unconvinced that radiography affords a suitable medium for measuring angles in such a multi-planed structure as the skeleton of the foot.

I am aware of the almost insurmountable difficulties involved in a mass examination of school-children's feet; but I feel that a more reliable assessment could be made by direct measurement, particularly with regard to the degree of varus or valgus of the metatarsus as a whole, which is of fundamental importance if the design of footwear for the growing child is to be improved.

London, N.7. JESSE W. J. TURVEY.

MEGALOBLASTIC ANÆMIA

SIR,—The article by Dr. Foy and his associates in your issue of June 21 contains much of great interest to those concerned with the problems of nutritional anæmias and vitamin deficiency states, especially the observation that there is an optimum dosage level above and below which no response can be obtained, and the relation of this observation to an effect on the intestinal microflora.

I have been keenly interested in this subject since 1939 when I first saw the anæmia of pregnancy so common in Assam. It appeared to me that this anæmia was not a specific disease, but only a manifestation in pregnancy of a disease or process which also affected men and non-pregnant women.

The identity of the condition was suggested not only by the clinical and laboratory findings but by the history given of a state, preceding or following pregnancy, indistinguishable from the clinical state of women in whom pregnancy had played no part, and of men suffering from anæmia and hypoproteinæmia with or without œdema and ascites, in whom there was neither renal disease nor vitamin deficiencies. Pregnancy made the treatment of women with this condition difficult, or unsuccessful, not because of a specific toxic factor due to the presence of the fœtus (the then generally accepted hypothesis) but because the inexorable demands of the growing fœtus for hæmopoietic substances and proteins finally exhausted the maternal reserves; and these reserves could not be replenished because of the primary "debilitating" process.

The common factor, the *disease*, presented itself as a long-continued mild diarrhœa, occasionally initiated by acute dysentery, which presented the peculiar feature that it was aggravated by protein foods. Many such patients deliberately avoided milk, meat, fish, and eggs, because it made the diarrhœa worse, the stools became more offensive, and they themselves felt more ill.

The end-result was hypoproteinæmia and anæmia of greater or less severity, with all the usual complications of œdema, ascites, and, in the long run, liver failure.

Arising from these observations and the basic assumption, it was argued that a disturbed microflora made essential amino-acids inutile, by conversion into other forms, or produced metabolites which were toxic, or, thirdly, competed successfully with the patient for essential amino-acids already in short supply in the diet. It was thought that the first two possibilities were the likeliest to be important.

An elementary attempt to establish the point was made by estimating daily the ratio of ferrous/ferric iron in the stool, with and without the addition of iron to the diet, it being considered that "putrefaction"—reduction—was the likeliest chemical process by which the amino-acids were rendered inutile. These results were rather inconclusive; for, whether the estimation was made with or without added oral iron, some healthy patients showed a ratio as high as that usually seen with the anæmic patients. It was decided that although the results were suggestive there were too many variables involved to make the estimation significant without a great deal more information which was not available.

Some patients were then treated with sulphapyridine (circa 1941–42); and it may be noted that the first severely ill patient with anæmia of pregnancy presenting in mid-pregnancy to go to term with a rising blood-count was one treated with sulphapyridine. These results were not obtained with sulphaguanidine, mappenide, or the later insoluble sulphonamides. Dr. Foy's findings with penicillin suggest the reason for the failure of the later sulphonamides to reproduce the effects with the less "efficient" sulphapyridine—namely, that they were indiscriminately lethal to both useful symbiotic organisms and the "deviationists."

Some of our patients from the plains were accustomed to use edible clays—alkaline bentonites—and a trial was made with a local acid clay to see if the pH of the bowel contents could be lowered and "putrefaction" checked. This produced no significant results.

It was found, incidentally, that patients with mild diarrhœa, or dysentery, treated with phthalylsulphathiazole or succinylsulphathiazole were apt to continue with abnormal stools unless they were also given vitamin-B complex with the idea of encouraging the growth of a normal flora.

In the main, although the hill people live on a diet consisting chiefly of rice or maize and very deficient in all proteins, fats, and vegetables, and although the children invariably show signs of vitamin-A deficiency and mild rickets, vitamin-B complex deficiencies rarely appear unless they develop dysentry or diarrhœa or are treated with sulphonamides for intercurrent infections. When deficiencies do appear, riboflavine deficiency is usually the first to be manifest. I have wondered whether this normal absence of B-group deficiencies is related to poor cooking—not merely that inadequate cooking destroys loss of the vitamin content of the food, but because uncooked starch is a better medium to permit refection.

Now that there is so much evidence to relate the state of the bowel microflora to anæmia, vitamin deficiencies, and possibly protein synthesis, and there is possibly a hint as to the characters of the organisms antagonistic to the establishment of a profitable symbiosis to be found in their sensitivity to sulphonamides and antibiotics, may we not expect in the future to discover a maximally helpful bowel flora, and even a new path to therapy in some cases by reinfecting a sterilised intestine with a helpful community of micro-organisms. The problem is not simply academic. Possibly more people are chronically ill because of biochemical pathogens than because of bacillary or protozoal bowel disease as ordinarily understood.

The Khasi Hills Welsh Mission
Hospital, Shillong, Assam.

R. ARTHUR HUGHES.

PROTECTION AGAINST WHOOPING-COUGH

SIR,—For years protection against whooping-cough has been referred to indiscriminately as "inoculation," "immunisation," or "vaccination." Now that vaccines giving promising results appear to have been found, ought we not to agree firmly on the name of the procedure? May I make a plea for the exclusive use of the word "inoculation" in propaganda regarding whooping-cough, since "vaccination" is by usage almost synonymous with vaccination against smallpox, and "immunisation" with immunisation against diphtheria?

Divisional Health Offices,
Ashton-under-Lyne.

W. J. ELWOOD.

FRACTURES OF THE NECK OF THE FEMUR

SIR,—I was interested in Mr. Stamm's simplification of the procedure for Smith-Petersen nailing, published in your issue of July 12. Complementary to his method, and therefore possibly worth recording, is a minor modification I have lately practised. Two patients suggested it to me. One had a suprapubic cystotomy, and the other in a period of confusion tore off her dressings. The practically bloodless approach to the nailing operation contributed to the idea.

A $^{3}/_{4}$-in. incision is made just below the lower edge of the trochanter. This can usually be felt through the skin, and even in fat patients direction-finding seems easier from the outside. A Steinmann pin is then passed down to the bone through a small cannula, and a hole is tapped through the cortex. This gives a hole large enough to introduce a guide-pin without its direction being dictated by that of the cortical perforation.

The Steinmann pin is withdrawn; and the cannula, held against the bone, leads the guide-pin down to the invisible hole in the cortex. The rest is simply the usual technique of blind nailing by feeling one's way. Two sutures close the incision.

Finally a piece of stockinette, pulled up over the thigh and dressings, adheres by pig. mastic. co. to the skin, and saves money on strapping. A loose turn of bandage round the waist ties through a hole in the top of this over the iliac crest as an added anchorage.

The incision must of course be enlarged in the rare event of nail extraction becoming necessary.

Cheltenham. L. HENRY.

HOSPITAL ADMINISTRATION

SIR,—I worked in hospitals, as medical superintendent and otherwise, for forty-five years and can perhaps claim some understanding of their management.

I view with dismay both the suggestion that hospitals should be placed under the government of laymen and the little interest which the medical profession has evinced in a matter which so closely concerns the interests of their patients.

A layman can control no more than the business and domestic affairs of a hospital; these are indeed necessary parts of its management, but entirely subsidiary to its main purpose, in which he can play no part at all. To place him in complete and immediate charge would therefore be a retrograde step fraught with danger to the conduct of the hospital. In no other sphere of human activity would a comparable proposal be for a moment contemplated. Would the paymaster ever be placed in control of a battleship, or a bursar of a college, or one with no knowledge of its processes in charge of a factory? The question of a medical hierarchy simply does not arise. It has always existed, for there are juniors and seniors everywhere; but it goes no further. A medical superintendent does not, and never has, exercised control over the professional work of the specialist staff.

Bickley. H. W. BRUCE.

ANTITHYROID ACTION OF P.A.S.

SIR,—Dr. Hanngren's preliminary communication (July 19) on the antithyroid action of *p*-aminosalicylic acid (P.A.S.) and the previously described occurrence of myxœdema in patients receiving this drug are important for two reasons. Firstly and obviously, there is the undesirability of producing myxœdema in any patient. Secondly and less obviously, there is the possible effect that depression of thyroid activity may have on the tuberculous process itself.

Fishberg[1] believes that hypothyroid persons often develop progressive tuberculosis. Rich[2] says: "Some of the experimental studies[3–5] tend to support the view that underactivity of the thyroid increases susceptibility to tuberculosis, but the matter requires further study."

In 1947, working on the hypothesis that if the B.M.R. could be reduced in tuberculous patients they would be resting more effectively, I administered thiouracil to three patients, all of whom had chronic active cavitated disease, and whose general condition, although poor, had been stationary for many months. One patient rapidly gained 12 lb. in weight, but the other two developed new lesions in 6 weeks, which stabilised on stopping the drug. The spreads were not expected (neither showed evidence of myxœdema). If the thiouracil was the cause, it would seem that a careful watch should be kept on the lungs of patients receiving antithyroid drugs.

If P.A.S. depresses thyroid activity, and if hypothyroidism lowers resistance to tuberculosis, we might expect to encounter evidence of escape from its bacteriostatic effect before treatment is stopped, especially in cases where its administration has been prolonged. We must ask then, is there anything to suggest that the tuberculostatic effect of P.A.S. can, in some circumstances, be partly offset by a side action which lowers the patient's resistance? Also, can this side action, if it exists, occur without clinically obvious manifestations of hypothyroidism? The concurrent administration of thyroxine in patients who are deteriorating on P.A.S. might be attended by the risk of masking thyroid damage.

Clearly, the implications of Dr. Hanngren's observations have set the tuberculosis physician a number of problems, the solution of which may be difficult.

London, S.W.17. F. A. NASH.

INSULIN HYPOGLYCÆMIA AND EOSINOPHILIA

SIR,—Dr. Lawrence has suggested (July 5) that the rise in the eosinophil-count of our insulin-treated psychotics is not necessarily related to hypoglycæmia and reactions thereto in hormone glands. He has observed similar rises in insulin-treated diabetics, and has ascribed these to local reactions to an injected foreign substance.

Neither Dr. Lawrence's patients (*Brit. med. J.* 1929, i, 597) nor our own (June 21) have shown clinical signs of local or general allergic reactions, and in our patients the rise in the eosinophil level was observed only after rapidly increasing doses of insulin, hypoglycæmic unconsciousness, and an eosinopenic reaction. Those patients in whom doses of insulin A.B. were inadequate in this respect, failed to show a rising eosinophil level.

Others have proved the efficacy of insulin as an adrenocortical stimulus, but the response to insulin is very complex and, unlike that to other stresses (e.g., chilling, emotional disturbances, and electroconvulsion therapy), it may give rise to eosinophilia. We do not claim to have proved that this rise is the result of hypoglycæmia, but have suggested that there may be a causal relationship between reactions to hypoglycæmia and the changes in the eosinophil-count.

SUCCINYLCHOLINE

SIR,—I read with great interest the article by Dr. Bourne and his colleagues in your issue of June 21. There are a few points in this paper with which I take the liberty to disagree.

The initial or single dose of succinylcholine chloride recommended by Dr Bourne and his associates was 1·1 mg. per kg. of body-weight. They state that this dose caused diffuse uncoördinated muscular contractions that were occasionally severe enough to be followed by muscular stiffness after recovery, and suggested that the use of succinylcholine might be unwise in certain fractures. They further state that "effective doses always caused respiratory arrest." This respiratory arrest was prolonged in 5 out of 546 patients.

They also describe the administration of succinylcholine chloride in a continuous intravenous drip at the rate of 10–12 mg. per minute.

I believe that both the single doses and the mg. per-minute doses recommended are unnecessarily high. We found in over 400 patients anæsthetised with sodium thiopentone that 10–30 mg. of succinylcholine chloride (or its equivalent amount of succinylcholine iodide) combined with topical anæsthesia of the larynx provided ideal conditions for endotracheal intubation. Mild muscular fasciculations were observed in only about one-third of the patients, none of whom complained of muscular soreness after recovery. Muscular relaxation was present for 2 to 3 minutes after these doses; apnœa lasting more than one minute was not seen in any of the patients.

Prolonged muscular relaxation was maintained in over 300 patients anæsthetised by sodium thiopentone

4. Schroder, G. *Beitr. klin. Tuberk.* 1930, 75, 61.
5. Kallos, P., Kentzler, J. *Ibid*, 1932, 79, 584.

plus nitrous oxide and oxygen for intra-abdominal operations by the continuous intravenous infusion of succinylcholine chloride in doses of 0·8 to 5·5 mg. (average 2·5 mg.) per minute. With this dosage excellent muscular relaxation could be maintained without apnœa in all patients. The degree of relaxation could be easily regulated to the needs of the surgeon by changing the drip-rate. Respiratory depth returned to normal within 3 to 5 minutes after the *infusion* was discontinued. No postanæsthetic muscular weakness was observed.

In the light of our satisfactory experience with much smaller doses we fail to understand the use of doses recommended in British reports. The goal of the administration of muscle relaxants should be muscular relaxation and not apnœa. With the previously used muscle relaxants occasional prolonged apnœa had to be accepted as an unwanted side-effect. With succinylcholine, if administered correctly, this complication can be avoided. Just because the apnœa observed after large (80–100 mg.) doses of succinylcholine only lasts 3–5 minutes in normal persons, there is no justification in using these doses.

The duration of the effect of succinylcholine, as it has been so well demonstrated by Dr. Bourne and his colleagues and by Evans et al.,[1] depends on the plasma-cholinesterase activity. Patients with decreased plasma-cholinesterase activity caused by disease or perhaps subclinical intoxication with anti-cholinesterase insecticides[2] have been encountered. If a dose adequate to produce muscular relaxation without apnœa in a normal person is given to a patient with decreased plasma-cholinesterase activity, apnœa might develop, but it will be of very brief duration only. Should, however, such a patient receive a dose 4 to 5 times as large, prolonged respiratory arrest will ensue. Such occurrences, always after the use of much larger doses than those used by us, were recently reported.[3]

Because of its controllability, wide margin of safety, and lack of side-effects, succinylcholine chloride proved to be the most desirable of all the muscle relaxants investigated by us. It would be unfortunate if, owing to the reports of side-effects caused unnecessarily by large doses, succinylcholine were prevented from assuming its well-deserved place in the armamentarium of anæsthesiologists.

Mercy Hospital, Pittsburgh,
Pennsylvania, U.S.A.
FRANCIS F. FOLDES.

SIR,—I am particularly interested in the experiences of Dr. Bourne and his colleagues with succinylcholine in abdominal surgery, and I would like to add my own observations.

I have used succinylcholine as a continuous drip in major abdominal surgery for some time, and I have found the technique simple and the results encouraging. A delay in recovery, mentioned as one of the chief disadvantages, has not been my experience.

It is clear that the quantity of drug required for any standard operation varies considerably from patient to patient, and cannot be based on weight and physique. In 150 operations the average dose has been 480 mg. per hour; but I have given as much as 900 mg. per hour, and as little as 125 mg. per hour has occasionally been effective. Long operations have required a slightly lower average hourly dose. As these doses are lower than those quoted by Dr. Bourne and his colleagues, it is possible that they have been using larger amounts than are necessary for adequate relaxation, and that recovery has therefore been delayed.

It is my practice to use a 0·1% solution of succinylcholine in normal saline. A test dose is first given slowly by intravenous drip to the conscious patient until some effects are felt, usually a twitching sensation down the spine. This is then rapidly followed by 0·5 g. of thiopentone, and the drip-rate is increased until good relaxation of the jaw has been obtained. The larynx and trachea are sprayed with a local anæsthetic solution and intubated with a cuffed tube. Nitrous oxide saturation is achieved by overventilation for 5–10 minutes with a 3 : 1 nitrous oxide/oxygen mixture, to which 4% of carbon dioxide has been added. Anæsthesia is then maintained with a mixture of 75% nitrous oxide and 25% oxygen. Respirations are assisted, but at no time are spontaneous respirations completely eliminated. The drip-rate is adjusted from time to time to produce the required relaxation for various stages of the operation. For example, during gastrectomy, a fast drip gives good relaxation during abdominal exploration, but during the anastomosis the drip is slowed and some muscle tone allowed to return. A knowledge of the speed and methods of the surgeon are helpful in obtaining the best results.

Using this procedure, good muscle tone has returned within 5 minutes of stopping the drip in almost all cases. Frequently the patient is opening his eyes and answering questions by this time. A steady rise in blood-pressure has not been a feature in these patients, but many have had a slow pulse-rate.

I cannot agree with Dr. Bourne that the technique is cumbersome, though constant vigilance is essential.

St. Helier Hospital,
Carshalton.
RONALD GREEN.

PREVENTION OF SEASICKNESS

SIR,—The correspondence on this subject (July 12, p. 93, and July 19, p. 146) has had, at least, one valuable result: Dr. L. N. Gay, of Baltimore, who has sponsored 'Dramamine,' a combination of 'Benadryl' and chlorotheophylline, admits that he does not know the effect of chlorotheophylline in motion sickness. There is indeed, as Professor Glaser has pointed out, no evidence that dramamine has any advantage in motion sickness over its component, benadryl. I think it is important that practitioners in this country should realise this, because a similar combination (this time of promethazine) with chlorotheophylline has been put on the market and widely advertised here. Promethazine alone is much cheaper, and there is no evidence that it is less effective.

University College Hospital Medical School,
London, W.C.1.
H. HERXHEIMER.

SIR,—The relative merits of hyoscine and of different antihistaminics in the control of seasickness will not be determined by argument, by appeals to work on animals, or by the multiplication of experiments in man where arbitrarily chosen doses of hyoscine and of this or that antihistaminic are compared.

It seems likely that it is to the hyoscine-like actions of antihistaminics that any anti-emetic effect they may have is due. The degree of hyoscine action, and its rate of onset and duration, varies, like the antihistaminic effect itself, from drug to drug. Thus in any critical evaluation of antihistaminics in the prevention of seasickness these two variables—time of onset and duration of protection—must be taken into account. A good deal of information is already available on these matters and could be utilised in the design of rigorous trials.

The major points at issue, however, can only be satisfactorily settled by the determination of dosage-response curves, in experiments which take account of these other variables. In brief, it is necessary to determine the relationship between different doses and the percentage

1. Evans, F. T., Gray, P. W. S., Lehmann, H., Silk, E. *Lancet*, 1952, i, 1229.
2. Marchand, J. F. *J. Amer. med. Ass.* 1952, 149, 738.
3. Gould, R. B. *Brit. med. J.* 1952, i, 440. Harper, J. K. *Ibid*, p. 866. Hewer, C. L. *Ibid*, p. 971. Love, S. H. S. *Anæsthesia*, 1952, 7, 113.

protection afforded by them, for hyoscine itself, and for one or more of the most promising long-acting antihistaminics with well-marked hyoscine-like effects. It would then be relatively easy to settle the minor question of whether the addition of chlorotheophylline to the antihistaminic molecule justifies the claims made for it.

An experiment of the kind suggested would be a somewhat formidable undertaking—especially if, as would be most desirable, all the observations were to be done on the same people. But it would be well worth the trouble involved and would be likely to yield information of a more valuable and reliable kind than is available so far.

Department of Pharmacology,
University of Leeds. W. A. BAIN.

TOXIC REACTIONS TO ISONIAZID

SIR,—Isoniazid (isonicotinic acid hydrazide) and iproniazid (1-isonicotinyl-2-isopropylhydrazine) are being given to many patients with tuberculosis throughout the United States and in many other countries. Toxic reactions to both drugs have been reported and, undoubtedly, more will occur. However, it is unlikely that any single investigator will observe enough of these toxic reactions in the next few months to warrant publication. The Committee on Therapy of the American Trudeau Society is anxious to collect reports of these toxic reactions, so that a consolidated report can be made available to the medical profession as soon as possible.

Any physician who is willing to submit such reports to the committee is asked to send a brief case-report to the Committee on Therapy, American Trudeau Society, Dr. D. T. Carr, 102–110, Second Avenue Southwest, Rochester, Minnesota. The report should include the patient's name or initials, his age, sex, race, diagnosis, weight, the drug administered and its dosage, the duration of treatment, and a list of other drugs being given at the same time. The toxic reaction should be described fully together with information as to its recurrence if the same drug was given later.

Copies of the consolidated report will be sent to all contributors, but will not be published in such a way as to preclude individual publications.

D. T. CARR.

REASON AND UNREASON IN PSYCHOLOGICAL MEDICINE

SIR,—I trust that the incidence of felo de se among psychiatrists will not show any steep rise following the publication of Dr. E. B. Strauss's Croonian lectures in your issues of July 5 and 12.

On second thoughts perhaps this might not be an unmitigated calamity. But it would be unfortunate if any considerable body of respectable citizens received the impression that it was necessary to go through the rather agonising permutations of metaphysical theory, indulged in by Dr. Strauss in his first lecture, in order to show that psychological medicine is, or can be, rational and scientific.

It is, of course, impossible to undertake any detailed criticism here. But as Dr. Strauss's main theme is based on the principle of causality, it is apposite to point out that in a recent book on scientific method given (astonishingly) a full-page review in the *British Medical Journal* (*The Common Sense of Science* by J. Bronowski) it is affirmed that causality is an outmoded idea—that in fact it is not now considered a scientific principle at all but "a faith," "a superstition," and merely "scholastic" like the medieval belief that everything is contained in the First Cause.

It is all very difficult, Sir. As the late Gilbert wrote and Sullivan sang: "Things are seldom what they seem, Skim milk masquerades as cream." How very true this is will be brought poignantly home to the most stubborn die-hard if, leaving verbal metaphysics aside, he will go and see the exhibition of the 20th-Century Masterpieces at the Tate Gallery. In paint as in words the tendency is the same.

London, W.1. FREDERICK DILLON.

TRAUMATIC DISLOCATION OF THE HIP

SIR,—In your issue of July 12 (p. 80) I am reported as advocating the prophylactic drilling of the epiphyseal plate in children following traumatic dislocation of the hip. If I gave this impression, let me hasten to correct it. In the first place, the incidence of aseptic necrosis in children is not known; and those authorities who, with good theoretical reasons, believe it to be much higher than in adults are none the less speculating without the evidence. However, once this complication *does* manifest itself in children, the anatomical conditions are such that revascularisation from the femoral neck cannot occur.

What I intended to convey was that in these circumstances it is reasonable to drill the epiphyseal plate. No vessels ever cross an intact epiphyseal plate; but once the integrity of the plate is destroyed by drilling, revascularisation by "creeping substitution" can occur. In children the articular cartilage can survive longer than in adults, so it is worth while.

Moreover, if the drilling is confined to the central portion of the epiphyseal plate, it does not cause premature fusion or interfere with growth.

Mansfield. E. A. NICOLL.

A BETTER NAME?

SIR,—Once again I note in your annotation of July 26 that we British, in our usual inimitable style, have coined an impossible word to describe something new. Heavens above—preregistrands! Surely there is some other way to describe newly qualified practitioners before being granted full registration. I admit that the word is more logical than, say, intern, but what a mouthful.

Newdigate, Surrey. W. F. WHEELER.

A.C.T.H. AND THE PIGMENT HORMONE

SIR,—It has recently been shown that A.C.T.H. and intermedin are closely related.[1–3] It has also been suggested that the chromatophorotropic effect may be safely used to determine A.C.T.H. in biological fluids, especially blood.[4] Dr. Morris [5] suggests, however, that the chromatophorotropic effect is not due to A.C.T.H.

Though this difficult question can be finally answered only by research it seems opportune to examine the evidence regarding these two conceptions.

The following points would indicate contamination of A.C.T.H. by a separate melanophore-expanding hormone:

1. Hogben [6] and Zondek [7–9] showed that the melanophores are under direct hormonal control by the pituitary gland. They found that, although the posterior lobe was apparently the best source of the hormone, significant amounts could also be isolated from the anterior lobe. Zondek showed that the intermediate lobe was apparently the primary site of production of the hormone, and hence coined the name intermedin. Only in primates that have no clearly defined intermediate lobe is intermedin produced mainly in the anterior lobe. This concept is also accepted by Allen, van Dyke, Houssay, Swingle, and Trendelenburg.

9. [illegible] Principle of the Pars Inter- [illegible] ...dular Physiology and Therapy. Chicago, 1935; p. 133.

2. Morris[5] has recently stated: "there is little doubt that the melanophore-expanding effects observed by various workers in A.C.T.H. preparations are due to contamination." He bases his conclusions on the following findings: (*a*) Waring and Landgrebe[10] have shown that the biological potency of intermedin is actually increased by heating with 0·1 *N* NaOH, whereas A.C.T.H. activity is rapidly destroyed by this reagent even at room-temperature; (*b*) intermedin can be obtained free of A.C.T.H. potency by the carbon adsorption process of Landgrebe et al.[11]; and (*c*) A.C.T.H. can be obtained free of intermedin activity by counter-current distribution between sec.-butanol and various aqueous acid solutions.

3. Li's school has recently separated intermedin from ascorbic-acid-depleting A.C.T.H. and has consequently assumed that they are different hormones.[12] Li has based his opinion on his experience in testing a number of sheep A.C.T.H. preparations which showed no direct correlation between their titre in adrenal ascorbic-acid-depleting activity and melanophore-expansion potency. Furthermore, he succeeded in separating intermedin from A.C.T.H. by the use of a discontinuous pH gradient on oxycellulose.[13] Besides this, he has pointed out that separation has also been achieved by zone electrophoresis on paper.[14]

The following facts would indicate the existence of a chromatophorotropic factor within the A.C.T.H. complex:

1. The chromatophorotropic factor is an integral part of pituitarian A.C.T.H. and its melanogenic effect in man becomes evident by skin pigmentation in three conditions: (*a*) A.C.T.H. overproduction in pituitarian Cushing's disease; (*b*) Addison's disease with increased A.C.T.H. output as a compensatory mechanism; and (*c*) pregnancy, where A.C.T.H. production runs high, judging by both blood examinations and the effect on rheumatoid arthritis. In contradistinction to these three "natural" conditions, melanoderma produced by over-treatment with A.C.T.H. is not necessarily a proof of the chromatophorotropic effect of A.C.T.H., since it may equally be due to contamination of our A.C.T.H. preparations with chromatophore hormone. This assumption is, however, refuted by the fact that purified and concentrated A.C.T.H. preparations have a chromatophorotropic effect in green-adapted frogs in doses down to 0·01–0·001 µg., whereas intermedin itself is active only in much higher doses.[1]

2. Determination of the chromatophorotropic factor in the blood of some hundred patients has shown that production of the chromatophorotropic factor in man always parallels the A.C.T.H. output as determined by the adrenal ascorbic-acid-depletion test (Sayers). Thus the chromatophorotropic factor is abundant in the blood of patients pigmented by chronic excessive output of A.C.T.H. (e.g., in Cushing's disease, Addison's disease, and pregnancy). It is also high, for short periods, in patients with acute conditions well known to produce A.C.T.H. (e.g., mental stress, heart stress, and operational stress). This parallelism is more than mere coincidence.[15]

3. The chemical properties of A.C.T.H. and intermedin are very closely related. For this reason both hormones always appear together in nature, and it is extremely difficult to separate them completely.[16] Characteristics common to both are remarkably high solubility in alcohol, which distinguishes them from all other pituitary hormones, and liability to rapid destruction by a special enzyme in blood and urine. For this reason, early investigations on the intermedin and A.C.T.H. content of biological fluids are no longer acceptable, unless they were carried out immediately after recovery of the fluid from the body or after immediate destruction of the special enzyme by acetone, heat, or similar procedures.

This evidence clearly indicates that A.C.T.H. and intermedin are separate factors, together constituting A.C.T.H. in nature. Separation is possible, just as separation of follicle-stimulating hormone (F.S.H.) from luteal hormone (L.H.) is possible; but just as we regard F.S.H. and L.H. as part of the gonadotropic hormone complex, so must we regard ascorbic-acid-depleting A.C.T.H. factor and the chromatophorotropic A.C.T.H. factor (intermedin) as one hormone complex—A.C.T.H.

Nature makes no distinction between these factors as the biochemist does. It seems, moreover, that the A.C.T.H. complex is composed of a multitude of factors possibly distinguishable by molecular weight and other physical properties. The existence of the following A.C.T.H. factors seems now to be proved:

A = Ascorbic-acid-depleting factor.[17]
B = Basic adrenal-weight-increase factor.[18,19]
C = Chromatophorotropic factor.[1,2]

Obviously in the future the potency of A.C.T.H. preparations should be gauged by the varying content of these factors, until a routine chemical method is found for separating them in the course of manufacture.

FEEDING DISORDERS IN INFANTS

SIR,—I should like to thank Professor Vining for his timely advice on infant feeding (July 19, p. 99). I could not agree more with his ideal feed of boiled milk and sugar, but my experience has been that 1 teaspoonful of sugar to 4 oz. is inadequate. Bottle-fed babies tend to be very constipated, unless considerably more sugar than usually advised is added to their feeds; one teaspoonful per pound of body-weight in 24 hours keeps the stools in good condition

Demand feeding, as Professor Vining says, is the feeding method of choice; but it may be quite impossible for the mother with two or three other small children. The infant's loud demands for food may (indeed often do) clash with the other children's meal. Also the baby who does not wake for a 10 P.M. feed will usually do so at 2 A.M.—a disturbance a busy mother can ill afford.

MARY ELLIS.
Hockley, Essex.

Parliament

Danckwerts Award Voted

ON July 28 the outstanding votes of the Civil Estimates were passed in the House of Commons. Class V—housing, local government, health, labour, and national insurance—includes provision for the Danckwerts award.

More Food or Fewer People

In the debate in the House of Lords on July 23 on the rising cost of food Lord BOYD-ORR, F.R.S., contrasted the price of food today and at the beginning of this century. Then food was cheap in this country, because as a largely industrial nation we could pay for all we wanted. In 1900 we were almost the sole buyers and about 80% of the world production of some foodstuffs came to this country. Today in the food-exporting countries there had been a rise in the population and in the standard of living; and these countries were now consuming more of their own food. Ten years hence Australia, for instance, might well have no food to export.

Again in 1900 it was thought that if people had enough cheap food—such as cheap meat, white bread, margarine, and jam—to satisfy their hunger the food problem had been solved. Now we realised that a more expensive diet was necessary for health and we had raised the standard of food consumption. Today not only did we have 49 million mouths to feed, but more expensive food was needed to put into these mouths. To meet this challenge we must increase home production. The Government had set its policy at a 60% increase in home

production. Lord Boyd-Orr believed that if we are prepared to spend substantial capital sums on bringing marginal lands into fertility we could produce 75% or 80% of our own food.

It was only prudent to rearm, but he thought it possible that in the long run it would pay us to devote some of the money now being spent on rearmament to increasing the home output of food.

Could we also, he asked, do anything to increase world supplies so that there were surpluses for us to import. Some people held that population would always increase faster than food production, and that we should never close the gap until birth control was generally accepted. He believed that birth control would be difficult to apply in time to prevent the population of the world from reaching 3500–4000 million. If W.H.O. really got going and eliminated diseases like malaria there would be a world explosion of population. But if full advantage was taken of the resources of modern agriculture and engineering, then the practical limit of food production was the amount of labour and money we were willing to put into it. In a food shortage we were the most vulnerable country in the world because we are so dependent on imports, but we were also a politically mature nation with a great Commonwealth, and we could offer an enlightened food policy to the world. If we did, he believed we should be astonished at the extent to which it would be accepted.

Publicity for Cancer Treatment

In the House of Commons on July 23 Brigadier FRANK MEDLICOTT pointed out that the number of cancer deaths in England and Wales had risen from 26,000 in 1900 to 80,000 in 1947. Admittedly in the early days of the century diagnosis was less accurate and modern medicine enabled more people to reach an age when cancer was more likely to affect them. But however optimistically the figures might be interpreted, it was clear that the present policy of reticence about the disease needed reconsideration. Only eighteen months ago the Central Health Services Council advised that it was undesirable for any general scheme of cancer publicity to be carried out by any central government organisation. A widespread feeling existed that cancer was always fatal. It was not yet generally realised how much progress had been made in the treatment of cancer during the last fifty years. The balance against giving more publicity to the importance of seeking advice for suspected cancer had probably so far been tilted by the medical profession's fear of a great increase in neurosis or cancer apprehension. He himself believed that view to be mistaken. Because no comprehensive cure had yet been discovered, doctors were perhaps unduly modest as to what had already been achieved. He also suggested that the cancer mortality was now so high that it was pointless to pretend that the disease was something which affected only a small number of people and that the less said about it the better. Secrecy might save a certain number of people from worrying about cancer, but at the same time it was condemning thousands to die many years before they need.

Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that, despite great improvements in the methods of treating cancer, we were forced to admit that, short of some revolutionary discovery, our chief hope lay in earlier diagnosis and treatment. Cancer was not a disease which could be made notifiable, but the Ministry encouraged registration of cases which came for treatment. Radiotherapy clinics were gathering valuable information. The emphasis was on education rather than on propaganda: but the problem was not easy because they were faced with deeply divided opinion in responsible medical quarters. The objections to a widespread direct education programme to the public were weighty. It would be wrong to have a national campaign based on fear. The Minister's Standing Cancer and Radiotherapy Advisory Committee had advised against a cancer campaign addressed direct to the public. But that reply did not mean that local health authorities should omit reference to cancer in their general health propaganda; for a great deal could be done through a more restrained type of information. That could appropriately be given by the local health authorities and the voluntary associations. The Government were considering what encouragement they could best give to these bodies. A start had been made with further education for doctors and medical students in the early recognition of cancer. The Ministry had six films for showing to professional audiences.

Cancer research was world-wide, and if any country discovered a cure it would be internationally shared. This country was playing its part: many teaching hospitals were specialising in this work and a great deal of research was being carried out through large numbers of medical, surgical, and scientific bodies, including the universities. Atomic energy research at Harwell had shown how nuclear physics could provide an important method of cancer treatment, and the new types of apparatus had already been ordered by National Health Service hospitals. She did not believe that merely spending money would necessarily bring results, but the Medical Research Council had increased its expenditure. In 1945–46 it spent about £6000 directly on cancer research, in 1951–52 £340,000, and this year it would spend £410,000, including £150,000 for financing the research activites of the Royal Cancer Hospital.

QUESTION TIME

Health Service Charges

Replying to a question Mr. OSBERT PEAKE, Minister of National Insurance, said it was not the practice for Government departments to publish the executive directions which they gave to their officers and he was not prepared to ask the National Assistance Board to make an exception to that rule by publishing the instructions given by them to local offices for dealing with cases of hardship in respect of dental, ophthalmic, and prescription charges other than those on National Assistance.

Flour Improvers

Mr. D. W. WADE asked the Minister of Food what progress had been made in the provision of an alternative to the agene treatment of flour; what evidence on this subject had been obtained from the United States of America; and what had been the results of his consultations with the Medical Research Council and the Research Association of Flour Millers.—Major GWILYM LLOYD GEORGE replied: The wide scope of the investigations makes it unlikely that they will be completed before the end of the year at the earliest. My department and the other departments concerned have from the outset maintained contact with the research and developments which have taken place in the United States of America.

Iodised Salt

Sir WALDRON SMITHERS asked the Minister what steps he was taking to implement the recommendations of the Medical Research Council for the addition of iodine to all salt for human consumption.—Major LLOYD GEORGE replied: The Food Standards Committee are considering representations arising from their report on this matter. They will, I hope, be able to advise me fairly soon how best to give effect to the council's recommendations.

Replying to a further question Major LLOYD GEORGE said that he could not say how soon a decision would be reached. He was advised that there were a good many objections of a technical nature, some of which were quite serious, but he would give the information as soon as possible.

Prescription Charges

In answer to a question, Miss HORNSBY-SMITH said that the gross amount accruing from the charge on prescriptions dispensed by chemists in June, 1952, was about £418,000.

Infectious-disease Beds in London

Mr. SOMERVILLE HASTINGS asked the Minister how many beds in hospitals in the London area were reserved for the treatment of infectious disease in 1949, 1950, and 1951; and how many were occupied.—Mr. IAN MACLEOD replied: The following figures are for beds allocated to the treatment of infectious diseases in hospitals in the London postal area.

Beds	*1949*	*1950*	*1951*
Allocated	3637	3453	2973
Occupied	1201	1162	929

Obituary

CATHERINE CHISHOLM

O.B.E., B.A., M.D. Manc., F.R.C.P.

Dr. Catherine Chisholm, who died on July 21 at the age of 74, was the first woman accepted by the University of Manchester as a medical student. She fully repaid this enlightened hospitality by her years of service on behalf of the women and children of Manchester.

Her father, Dr. Kenneth Chisholm, believed in education for women, and his daughter had graduated in arts at the University of Manchester in 1898, after having won the Bishop Lee Greek Testament prize, before she asked for permission to study medicine. She took her medical degree in 1904 and after holding house-appointments in London and Yorkshire she settled in practice in Manchester.

Her special interest in the care of women and children was recognised by her appointment in 1914 as physician for children to the Northern Hospital, Manchester. The same year the medical women of Manchester opened a small hospital for the "more effective treatment of babies and very young children suffering from diarrhœa and other gastro-intestinal disorders." They felt that in a general hospital it was not always possible to offer these small patients the special attention and accommodation they needed. The number of patients was at first limited to 12, and the cost for the first year was estimated at £800. From this modest beginning grew the present Duchess of York Hospital for Babies which now has over 100 cots. In 1919 Dr. Chisholm gave up private practice, for besides being senior medical officer to the new Babies' Hospital she had been appointed consultant for children at the Hope Hospital, Salford, and clinical lecturer in children's diseases at the University of Manchester. For 36 years she was also medical officer to the Manchester High School for Girls, and she published a monograph on *The Medical Inspection of Girls.* She continued this side of her work as a member of the court of Manchester University where she did much to safeguard the health of women students.

[*F.W. Schmidt, Manchester.*

From 1928 to 1929 she was president of the Medical Women's Federation. In 1935 she was appointed C.B.E., and in 1949 the Royal College of Physicians of London chose her as the first woman to be elected to their fellowship under the by-law permitting the election of doctors who are not members. Although her activities had been curtailed during the past year, she was as interested as ever in what was going on, especially in the Duchess of York Hospital where her name has been given to the premature baby ward. She retired from the management committee only last November.

To this record of honourable service and official distinctions the words of her friends add colour and warmth.

"As a doctor," writes S. K. G., "Catherine Chisholm treated her patients, however young, as human beings and quickly secured their interest and coöperation. This recognition of the needs of the young child was one reason for the early success of the Manchester Babies' Hospital where the facilities and nursing care were, under her firm guidance, specially adapted for the small patients—a fact soon recognised and welcomed by the mothers who came with their babies. As a teacher, her students were carried forward by her intense interest and vitality, by her eager grasp of new methods of diagnosis or treatment, and her ability to stress even the smallest details of hygiene and nursing care so as to weld the treatment of the child into a complete whole. As a senior colleague, she was always ready and willing to listen or offer suggestions, while problems of clinical or administrative importance would be discussed with the whole staff. As a friend her support and encouragement knew no bounds. She would go out of her way to help people. Many medical women—and men too—owe their advancement to her, for she opened the way and enabled them to move forward with confidence. I remember with warm gratitude her support during difficult times, her pleasure in the achievements of others, and her unfailing interest in the personal life of those around her. Many children, and those now grown-up as well, will always think with affection of 'Chisio' and her breezy visits, sometimes with an unexpected gift such as a longed-for book. For her wide knowledge, her sound wisdom, and her warm good fellowship she will be missed by many all over the country."

C. E. W. mourns her friend in the words of the Gael: Yesterday a mountain in my sight, and today, my grief, a shadow.

"The personality and intellect of Catherine Chisholm," she continues, "were indeed a mountain of an infinite and contradictory variety of aspect. She had Highland imagination in her appreciation of literature and the arts, especially music, and in her intuitive understanding of the child and the rebel. She had Lancastrian shrewdness in assessing the worth of others, so that she gathered round her generation after generation of able juniors. She had the proper male contempt for domestic trivia, and an intensely feminine interest in dress and manners. She had tremendous courage, whether putting a needle into a baby's longitudinal sinus, driving on to a rickety Highland ferry, or boarding some august philistine for his subscription or his signature. She was the bonniest fighter—went in without fear, stayed in without loss of temper or dignity, and won without malice. With courage went generosity as reckless, shown in nothing more than in her friendships, which were many and embraced not only friends but their children and grandchildren ripening with their ripening years, and extended also to her staff in hospital and household.

"She looked and spoke charmingly at the dinner given in her honour by the Manchester branch of the Medical Women's Federation after the award of the fellowship of the Royal College of Physicians. This was the same Catherine Chisholm who had cowered under the weather gunwale on the way to Mull in a squall, or sat, booted, be-knapsacked, and happy on Helvellyn or Snowdon, or some height in Ireland or abroad, after a morning's scramble. At the day's end the 'crack' was seldom of 'causes,' for she could bandy the best of nonsense, solve puzzles, play children's games, and follow the complications of a Wild Western at the cinema.

"Yesterday a mountain, today a shadow—tomorrow perhaps a legend, and all legends have served as rallying cries."

Births, Marriages, and Deaths

BIRTHS

BROWN.—On July 23, at the Sussex Maternity Hospital, Brighton, to Elizabeth (née Cumberlege), wife of Dr. P. B. Brown—a son.

BUXTON.—On July 24, at King's College Hospital, to Diana Margaret (née Borrow) and Dr. Roger St. John Buxton—a son.

DAVIES.—On July 24, at Churchill Hospital, Oxford, to Alison, wife of Dr. J. O. F. Davies—a daughter.

EDNEY.—On July 14, at Faversham, to Mary, wife of Dr. Roy Edney—a daughter.

FAIRBAIRN.—On July 19, to Marcia, wife of Dr. A. S. Fairbairn—a daughter.

FISHER.—On July 21, in Belfast, to Sheila (née Penny), wife of Dr. Oliver D. Fisher, M.R.C.P.—a son.

GELLATLY.—On July 16, at Perivale Maternity Hospital, to Audrey (née Norris) and Dr. Edward Gellatly—a son.

WOOTTON.—On July 14, at Hammersmith Hospital, London, to Veryan, wife of Dr. I. D. P. Wootton—a son.

MARRIAGES

BENNISON—UNDERWOOD.—On July 19, Robert John Bennison, M.B., of Harrogate, to Kathleen Mary Underwood, M.B., of Nottingham.

FRANKS—DOUHAN.—On July 19, in London, Raymond Basil Franks, M.R.C.P., of Wimbledon, to Ulla Margareta Douhan, of Stockholm.

GREY TURNER—TOMLINSON.—On July 26, Elston Grey Turner, M.C., M.R.C.S., of Huntercombe Manor, near Taplow, Buckinghamshire, to Lilias Tomlinson, of Credenhill Court, Herefordshire.

DEATHS

CAMAC.—On July 19, James Camac, M.B. Belf., of Church Gresley, Derbyshire.

CHISHOLM.—On July 21, at 34, Broadway, Withington, Manchester, Catherine Chisholm, O.B.E., B.A., M.D. Manc., F.R.C.P.

NOBLE.—On July 22, at Lowthorpe, 31, Queen's Park Avenue, Bournemouth, John Allen Noble, M.C., M.A., B.M. Oxfd.

PYRAH.—On July 9, in hospital, Reginald Smith Pyrah, M.B. Leeds, of Farnley, Leeds.

Notes and News

RESEARCH IN SCOTLAND

At the start of the National Health Service in Scotland the endowment funds of the voluntary hospitals were transferred to the new hospital boards of management. The funds now amount to some £13 million and the Hospital Endowment Commission has been considering, under the chairmanship of Sir Sydney Smith, how they can best be used. Part of the money, the commission consider, should be set aside to provide amenities for hospital patients and staff beyond what the N.H.S. "can reasonably be expected to finance." The substantial remainder, they suggest, should be used to finance medical research in Scotland, and they have set out their proposals in a white-paper to the Secretary of State for Scotland (H.M. Stationery Office. 6*d*.).

The commission recommend that a small number of trustees, broadly representative of the whole of Scotland, should be set up under statutory powers to work in close association with the Advisory Committee on Medical Research in Scotland. They estimate that the funds likely to be available under the trustees would produce an income of some £120,000 a year. Any research-worker or team would be entitled to apply for help, and the commission think that research should be looked at in its widest sense and "not merely as a matter of laboratory investigation."

Many boards of management have only small endowments or no endowments at all at present, while others have large funds for which there is no sufficient outlet. The commission would like to see part of the money redistributed in such a way that every board of management will have reasonable funds at its disposal for research as well as other purposes. They propose to provide also for the constitution of small funds under the control of each regional hospital board.

THE AGE OF ENTRY TO NURSING

The leaders of the nursing profession have long believed that girls entering nursing training should not be under the age of 18. In August last year recruitment had reached the highest figure ever known up to that time (though it has since gone a little higher), and the General Nursing Council and the Ministry of Health agreed that a regulation should be made—which is coming into force on Aug. 1, this year—fixing the minimum age of entry at 18. Girls under that age who have begun their training will be allowed to continue. Those who have joined cadet schemes or prenursing courses will have to wait six months longer before beginning their hospital training, but will not otherwise be affected. In hospitals where recruitment is likely to be seriously reduced the G.N.C. have discretion to relax the rule until the situation adjusts itself.

APPROVED NAMES FOR DRUGS

The British Pharmacopœia Commission has issued the following new supplementary list of approved names:

Approved name	*Other names*
Alphameprodine	α-3-Ethyl-1-methyl-4-phenyl-4-propionoxy-piperidine.
Betameprodine	β-3-Ethyl-1-methyl-4-phenyl-4-propionoxy-piperidine.
Hydroxyprocaine	2-Diethylaminoethyl 4-aminosalicylate.
Isoniazid	*iso*Nicotinhydrazide. Cotinazin; Hydrazid; Mybasan; Pycazide; Rimifon; Tubomel.
Penethamate hydriodide	Benzylpenicillin 2-diethylaminoethyl ester hydriodide. Estopen.
Pyrimethamine	2 : 4-Diamino-5-*p*-chlorophenyl-6-ethylpyrimidine. Daraprim.

THE GOLD MINERS OF WEST AFRICA

The health of the mining community of the Gold Coast is the subject of a report [1] by Prof. G. Macdonald to the Ross Institute Industrial Committee. The gold mines (together with others that work bauxite, manganese, and diamonds) employ some 34,000 persons, of whom about 12,500 work underground. A large number of these are seasonal workers, who form part of an annual migration of 200,000 persons from the healthy but infertile interior to the fertile coast. The migration, which has been going on for centuries, starts in August and September, and the return journey is in the spring. The journey of over 350 miles is made partly on foot, partly on overloaded lorries. Three major rivers have to be crossed by ferries; these are quite inadequate, and lorries may be held up for a week. During the long journey neither feeding nor sanitary arrangements are organised. Both during the journey and on arrival at the coast the labourer depends on agents and moneylenders for his immediate necessities, and usually he starts his season's work heavily in debt. Yet these migrants are the wealth of the Gold Coast Colony; so, as Professor Macdonald points out, both the health and the economy of the Colony would benefit if the journey could be made "reasonably civilised for all." But it is not clear whether he regards this as more properly a task for the mine owners or the government.

At the mines themselves the hospital arrangements are "creditable." But there is no organised industrial or preventive medical service amongst the community. Hot underground workings impose a severe environmental strain on many workers, and the most important industrial hazards are probably accidents and tuberculosis. Many of the miners live in villages where housing, sanitation, and feeding are far from adequate; but some mines have excellent housing arrangements for their labour and well-run canteens. Many of the men prefer to live in squalor in the villages, often amongst a tribal group, where a natural leader maintains the tribal organisation and discipline; but such leaders apparently fail to instil standards of conduct and hygiene suitable to an industrial community.

The Gold Coast miners present a fascinating problem in social medicine. The Ross Institute sees clearly the elements of the solution, and, as an outside body, should be well fitted to bring about the necessary coöperation between the mine owners, the government, and the miners and so create new attitudes to health. In this, as in nearly all difficult public-health problems, much rests on education.

---

University of London

The title of professor emeritus of bacteriology has been conferred on Prof. S. P. Bedson, F.R.S., and the title of professor emeritus of chemical pathology on Prof. J. R. Marrack, on their retirement from their chairs at the London Hospital Medical College.

The title of professor of pharmacology and therapeutics has been conferred on Dr. C. A. Keele in respect of his post at the Middlesex Hospital Medical School, and the title of professor of chemical pathology on Dr. N. H. Martin in respect of his post at St. George's Hospital Medical School. The title of reader in biochemistry has been conferred on Mr. William Klyne, PH.D. (Postgraduate Medical School of London), the title of reader in bacteriology on Dr. B. W. Lacey (Westminster Medical School), and the title of reader in morbid anatomy on Dr. A. D. Morgan (Westminster Medical School).

Royal College of Physicians of Edinburgh

At a meeting of the college on July 22, with Dr. W. A. Alexander, the president, in the chair, the following were elected to the fellowship:

Daw Yin May, Maung Shwe Zan, W. J. G. Barrie, J. W. Rae.

The following were elected to the membership:

A. F. S. Perera, Mohd Ayub Khan, W. S. Watson, W. J. Abel, Nimai Krishna Mitra, Andrew Bogdan, G. H. Templeman, Arthur Jarrett, M. W. J. Boyd, N. S. Chalk, Pathiyil Karthiyayani Krishnankutti, Sureshwar Prasad Jha, J. B. Cromie, H. G. Morgan, C. D. R. Pengelly, Harry Altman, Eveline P. Forbes, Leo Schamroth, L. H. Moffin, P. G. Aungle, Janet L. P. Hunter.

Queen's University, Belfast

At recent examinations the following were successful:

M.D.—Sarah L. Campbell, R. A. N. McMath, Thomas Wilson (with commendation); R. N. Beck, P. J. Blaney, E. W. T. Henry, J. C. Hewitt, R. J. Marshall, Frances L. J. Robinson, K. L. Stuart, A. P. Trimble.

M.B., B.Ch., B.A.O.—F. C. O. Allen, R. F. C. McDowell, J. J. H. Stewart (with second-class honours); C. A. C. Abraham, D. A. Aiken, Goordeealsing [illegible] bin, S. C. Bateman, R. C. Bloomfield, C. [illegible] P. Boyle, Eileen S. Browne, John Carroll, T [illegible] orkey, C. E. Cosgrove, E. C. Cowan, G. E. Crawford, Margaret H. Dales, S. N. Donaldson, Domnall Duffin, Desmond Duignan, T. L. Dunn, D. S. Fullerton, Dorothy Gilpin, Florence C. Gordon, W. H. Graham, T. M. Hannigan, K. K. A. Hofheinz, H. B. Kean, John Lowry, Matthew Lowry, S. J. H. Lowry, W. N. C. McCleery, J. W. McKay, T. J. McLister, Elizabeth G. H. McLucas, J. B. H. Martin, J. S. Y. Mathewson, E. S. Mitchess, James Moore, A. L. Murphy, Frances M. Murphy, R. C. W. Murphy, Betty Nicholl, Margaret Nicholl, R. M. Nicholl, P. J. O'Neill, B. Z. Rosensweig, David Ross, G. M. Scott, Anthony Smyth, Mabel M. Stevenson, E. M. W. Stuart, Zoe Waddington, Margaret G. Warwick, Madge G. Watson, Mary J. Watson, A. G. C. Wilson, A. J. Woods, J. H. Woolf.

D.P.H.—John Andress, T. L. Gracey, G. A. Kernohan, Anne W. Kilpatrick, E. I. Mulholland, C. R. C. Rainsford, Sarah E. M. Sherrard, H. P. Swan.

Royal College of Surgeons of Edinburgh

At a meeting of the college held on July 21, with Prof. Walter Mercer, the president, in the chair, the following were admitted to the fellowship:

V. P. Amato, Manilal [illegible] Chand Bhandhela, [illegible] J. R. Conacher, [illegible] Adly Hammouda [illegible] G. Munro, Nanalal Ranchhodji Patel, A. I [illegible] William Seright, B. L. Shaff, Abdel Hamid Shouman, E. M. Sparrow, K. S. Stewart, J.G. Stonham, Willoughby Wilson.

Scottish Conjoint Board

At recent examinations of the board of the Royal Colleges of Physicians and Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow the following were successful:

Ranjit Singh Ahluwalia, Mavis F. Anderson, F. J. Badenhorst, J. B. B. Baird, C. E. Barth, G. A. C. Binnie, E. H. Brown, D. G. Chambers, Brian Cornes, W. A. Dalgleish, E. A. Ehlinger, Sydney Fogel, Brenda Gale, Colina Graham, Ruth E. Graham-Yooll, J. M. H. R. Hardy, A. R. Isaac, Amirali Husein Kassam, Viljoen Kritzinger, C. H. Lalgee, Pamela M. Lambden, P. A. Lowe, W. A. Mahon, Pearl K. Malasky, Christine W. Mann, R. W. S. Miller, E. C. Moffat, J. I. Morrison, J. A. McIlvride, Agnes F. Mackay, Arnold Orwin, Joyce E. A. Ovens, Hedwig M. M. Papigay, Audrey Pilbeam, Jean M. Price, R. A. W. Ratcliff, Margaret H. Rodger, Enid Sagar, Ralph Shabetai, Thelma D. Standing, Robert Steele, Alexander Stevenson, Cyril Ward, M. H. Weinberg, M. M. Wiener.

Royal College of Obstetricians and Gynæcologists

At a meeting of the council held on July 26, with Dame Hilda Lloyd, the president, in the chair, the following officers were elected:

President, Mr. A. A. Gemmell; vice-presidents, Prof. Gilbert Strachan and Mr. A. J. McNair; hon. treasurer, Mr. A. C. H. Bell; hon. secretary, Mr. H. G. E. Arthure; hon. librarian, Mr. A. J. McNair; hon. curator of the museum, Mr. Aleck Bourne; hon. treasurer of the Australian regional council, Prof. Bruce Mayes; hon. treasurer of the New Zealand regional council, Mr. H. K. Pacey. Sir Stanford Cade was invited to attend meetings of council as representative of the council of the Royal College of Surgeons.

The following were elected to the membership:

Janki Devi Arora, Lily Arratoon, J. L. M. Bean, Anil Chandra Bhoumik, C. H. Borsman, G. H. Burgess, G. G. Champion, Sivaccolunthu Chinnatamby, G. R. Clare, J. F. Correy, N. K. Crooke, G. E. Cummins, A. M. Dawson, R. D. De Vere, D. T. Dodds, C. P. Douglas, Robert Dowie, Sunit Kumar Dutt, Aileen C. Foley, M. S. Forrest, D. F. P. Gordon, W. J. Gordon, J. J. Handler, Alexander Hunter, Daphne M. E. Kayton, I. A. McDonald, Margaret W. Macgregor, T. P. Magee, T. M. McNie, A. G. Mathew, P. R. Myerscough, J. G. O'Sullivan, Marjorie M. Paterson, Alexander Persey, Evelyn Peters, G. W. Prueter, Delmont Puflett, Marie Quadros, M. B. Quane, Bibhuti Bhusan Rakshit, Harry Rees, Dia Seif-Eldin, C. A. Simmons, E. L. Trott, Mary E. Walker, R. A. Warren, H. B. Watson, J. A. Williams.

Royal Australian College of Surgeons

Alan Newton prize.—This essay prize was established last year in recognition of the services to the college of Sir Alan S. Newton.

It is to be offered biennially to fellows of the Royal Colleges of Surgeons of Australasia, of England, of Edinburgh, in Ireland, and of the Royal Faculty of Physicians and Surgeons of Glasgow.

The subject for the first essay is to be the Pathology and Surgery of Diseases of the Parathyroid Glands, and entries should reach the secretary of the college on or before Dec. 1, 1954.

Royal Medical Benevolent Fund

At the annual general meeting of the fund held on July 24 the following officials were re-elected: president, Lord Webb-Johnson; hon. treasurer, Mr. F. A. Juler; and hon. secretary, Dr. R. Cove-Smith. During 1951 £36,500 was distributed in grants, gifts, and annuities.

Blood Donors

There are now more blood donors in England and Wales than at any time since the late war. During the March quarter this year 17,269 new donors joined the National Blood Transfusion Service bringing the total to 470,574. Over 170,000 more donors are needed to keep pace with the growth of the service and to provide a reasonable reserve of blood plasma.

W.H.O. Tuberculosis Appointment

Dr. Johannes Herman Holm, of Copenhagen, has been appointed chief of the tuberculosis section of the World Health Organisation. He succeeds Dr. J. B. McDougall who has held the post since W.H.O. was established.

Dr. Holm, who was born in 1902, studied medicine at the University of Copenhagen. He has lately obtained an M.P.H. at Harvard. Among the positions he has held are the following: chief of the tuberculosis division of [illegible] consultant to the Danish national [illegible] U.S. Public Health Service, chair[illegible]mittee on tuberculosis, and director of the International Tuberculosis Campaign.

Société Française de Biologie Médicale

This new French society has lately been set up under the presidency of Prof. Henri Benard. The secretaries are Dr. M. Lamotte, 48, rue du Docteur Blanche, Paris, and Dr. M. Durupt, 20, rue de la Pompe, Paris.

The Largest Medical Library

Lieut.-Colonel Frank B. Rogers has been appointed director of the recently established Armed Forces Medical Library in Washington. Colonel Rogers has served since 1949 as the director of the Army Medical Library, which is the nucleus for the new establishment. The new library is to serve as a central medical library for the United States Army, Navy, and Air Force, and as a national library for medicine and related sciences.

Committee on Venereal Infections and Treponematoses

At the fourth session of the World Health Organisation's expert committee on this subject, which opened in London on July 28, speakers reviewed the work of W.H.O. in this field during the last four years which has ranged from demonstration projects against the venereal infections to mass treatment campaigns against yaws in Indonesia and Thailand, and against bejel in Iraq. The experience gained in the treatment of treponemal infections by repository penicillin therapy was also discussed.

The Doctor's Signature

The *Manchester Guardian* of July 25 records that at a meeting on the previous day the London Executive Council was informed by its general benefits committee that on some prescription forms the doctor's signature is indecipherable. If the doctor for any reason is liable to a surcharge it is then impossible to trace him. The council has decided to ask the Executive Councils Association to consider whether the Ministry of Health should be asked to put a distinguishing number or mark on prescription forms so that the practitioner can be readily identified.

Lord Horder has accepted an invitation to become the first president of the United Hospitals Festival Choir.

Appointments

Howat, D. D. C., M.B. Lond., D.A.: consultant anæsthetist, St. George's Hospital group, London.

Pleydell, M. J., M.C., M.D. Lond., D.P.H.: deputy county M.O.H., Northamptonshire.

Rutherford, H. W., M.B. Aberd., D.P.H.: asst. tuberculosis officer, North-Eastern R.H.B.

Birmingham Regional Hospital Board:

- Ansari, A. H., M.A. Camb., M.R.C.S., D.M.R.D.: asst. radiologist, Dudley and Stourbridge and West Bromwich group of hospitals.
- Kershaw, R. A., M.B. Manc., M.R.C.P.: asst. chest physician, South Worcestershire group of hospitals, and Worcestershire county council.
- Paul, M. B., M.A., M.D. Camb.: consultant chest physician, Burton-on-Trent group of hospitals.
- Sanderson, J. M., M.B. Birm., F.R.C.S.: part-time consultant thoracic surgeon, Stoke-on-Trent group of hospitals.

East Anglian Regional Hospital Board:

- Chalmers, R. D., M.R.C.S.: asst. chest physician, Peterborough chest clinic.
- Love, W. J., M.B. Belf.: anæsthetic registrar, United Norwich hospitals.
- Wolff, F. W., M.B. Durh.: medical registrar, West Suffolk General Hospital.

Manchester Regional Hospital Board:

- Brown, C. P., M.B. Manc., D.A.: consultant anæsthetist, thoracic surgery team, Blackpool.
- Hassall, Harold, M.B. Manc., F.R.C.S.: consultant general surgeon, South Cheshire hospital centre.
- Marsden, H. B., M.B. Manc., D.C.H.: asst. pathologist, Salford.
- White, T. A., M.B. Birm., D.C.P.: asst. pathologist, Withington Hospital, Manchester.

North-East Metropolitan Regional Hospital Board:

- Brimblecombe, F. S. W., M.D. Lond., M.R.C.P., D.C.H.: part-time consultant pædiatrician, Harold Wood Hospital.
- Cohen, E. L., M.A., M.B. Camb.: part-time consultant dermatologist, Oldchurch Hospital.
- Edkins, J. R. P., M.D. Manc., D.P.M.: consultant psychiatrist, Brentwood Mental Hospital.
- Gray, P. W. S., M.B. Lond., D.A.: consultant anæsthetist, Chase Farm Hospital and other hospitals within the group.
- Marks, Morton, M.R.C.S., D.L.O.: part-time consultant E.N.T. surgeon, Mile End and St. George-in-the-East Hospital.
- Sefton, Louis, M.R.C.P.E.: part-time consultant dermatologist, Whipps Cross Hospital.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

THERAPEUTIC TRAUMA OF THE BRAIN*

P. MACDONALD TOW
M.B., Ph.D. Lond.
BEIT MEMORIAL RESEARCH FELLOW
From the Nuffield Department of Surgery, University of Oxford

IT has not always been accepted that the brain was the organ of mind; or, to put it less equivocally, that it was the physical organ of any psychological activity. This alone may explain why manipulation of the organ was not proposed earlier as a cure for diseases of the psyche. One of the early pronouncements on the subject was made by Hippocrates:

> "It ought," he wrote, "to be more generally known that the source of our pleasure, our merriment, laughter, and amusement, as of our grief, pain, anxiety and tears, is none other than the brain. It is especially the organ which enables us to think, see and hear, and to distinguish the ugly and the beautiful, the bad and the good, the pleasant and the unpleasant. Sometimes we judge according to convention; at other times according to the perceptions of expediency.
>
> "It is the brain, too, which is the seat of madness and delirium, of the fears and frights which assail us, often by night, but sometimes even by day; it is there where lies the cause of insomnia and sleep-walking, of thoughts that will not come, forgotten duties, and eccentricities."

But it was over 2000 years before the connection was therapeutically exploited.

A trial of cerebral surgery was made in 1890, following on the animal experiments of Goltz. The pioneer was G. Burckhardt, physician in charge of a small Swiss mental hospital, who removed part of the temporo-parietal cortex in a few severe psychotics. But, though one patient appears to have been considerably benefited, Burckhardt met with much opposition and his work ceased and was forgotten. Very different was the reception accorded Egas Moniz of Lisbon, sixteen years ago, when he described the results of operating on the brains of 20 insane persons. Far from receiving intense opposition, his method was quickly taken up by Freeman and Watts in America and others elsewhere, and was soon well on its way to extensive trial. Yet, though thousands of patients have been leucotomised in the succeeding years, we are still far from certain of the value of the operation: as Professor Lewis (1950) has aptly put it. "Some of the successes attained by the operation in apparently hopeless cases indicate that its risks and crudity do not put it out of court; it is still in many respects on trial, but has respectable testimony in its favour."

EFFECT OF LEUCOTOMY

If these operations are traumatic, where exactly is the trauma? There is, of course, the surgical trauma. Apart from a few excursions down into the thalamus, this, up to now, has been confined to the frontal lobe; but this trauma is deliberate. There may be minor accidental trauma to the autonomic system and to purely intellectual activity: but the body as a whole and all the senses are unimpaired. The major damage is to certain aspects of the character or personality.

For almost a decade after the initial dramatic success of Moniz and Freeman, and, curiously enough, especially towards the end of that period, it was repeatedly and indignantly denied that the operation resulted in any trauma to the person as a whole. Patients were apparently being cured right and left, and were *often* discharged from hospital to the ordinary social and domestic backgrounds of everyday existence. Such patients were in fact sent away from the physicians' constant observations; and with so few workers in the field it may be understandable that their later fate was lost sight of in the zeal to cure more urgent cases.

Moniz published his first communication in
In 1939 appeared the classic monograph of Pro
Rylander on his study of patients who had had
frontal lobes removed for tumour—the first full ps
logical study of surgical cases of this sort. His num
findings included not only psychological data fr
series of tests but also an account of the various a
malities of behaviour which he discovered onl
visiting the homes of the lobectomised subjects.
for some reason his example was not heeded, and
leucotomy patients were rarely given anything
than a conventional psychiatric examination.

That the operation of leucotomy is therapeu
now beyond all doubt. It produces a consid
amount of relief in intolerable mental illness. The
disorderly schizophrenic frequently becomes quie
manageable; the depressive is often relieved
sadness and suffering; the tense obsessional be
relaxed; and the anxious hypochondriac ceas
complain. Often, though not always, the distr
symptoms which form the core of the presenting
are removed.

The topical question, however, is not how much
these operations will do, but rather how much
they may cause.

HOW MUCH HARM?

I believe that in any large hospital for the c
insane—say with 2000 beds—one could justifiably
out the hundred worst patients and deprive th
part of their frontal lobes. One would inevitably
certain amount of good, and the little bit of ba
would do, also inevitable, would in such cas
negligible. It would certainly be more logical
leucotomising every obsessional patient ill for more
two years.

In well-preserved patients with the common for
neuroses the results from the purely clinical po
view are about the same (Tow 1950); but it is in
cases that one sees after operation the various
malities of temperament and character which a
meat of the present arguments about the do
ethics of the operation. Some of these abnorm
such as emotional barrenness, gross egocentricity
of responsibility towards others, and lack of ap
tion of moral and spiritual values, are in particul
basis of outcries about the wickedness of the proc

I have suggested one reason why such obv
serious complications passed unnoticed at first. An
probably, was that gross abnormalities of this ki
definitely rare; so in the early days the relatively
number of cases then available could not yield
such examples. A further reason was that most of
early patients were in the worst wards of a
hospital, and among a group of dirty, degenerate s
phrenics it is hardly surprising that one of
leucotomised, might not be conspicuous by his
rude or inconsiderate table manners. At any rat
asocial tendencies and inconsiderate behaviour
hardly be observed with any thoroughness, and no
significance would be attributed to them, agains
abnormal psychological environment of the c
hospital ward.

The background against which the early postope
changes were observed was in fact the worst p
for their detection, and the entirely hopeful and
peutic orientation of the observers may not have
discovery of the type of change which sometimes occ

But it was not long before the operation was
tively performed on sane patients—patients with v
severely disabling neuroses, but with a basic perso
still essentially intact. What happens if we i
frontal cortex in such patients? Roughly the sa
with the psychotics, if they have been well sel

---

* From an address to the Medical Society of London.

In half, the illness is relieved, and perhaps a few are cured. The others are essentially unaltered; they may be slightly better, or, more rarely, slightly worse.

Here again similar circumstances vitiated the results. A neurotic was seen, for example, in the consulting-room and recommended leucotomy; when he was seen later the operation had produced the effect desired. Often, however, it had also produced an undesired effect, a certain damage to the personality, and this was missed because the symptoms and signs which made it up did not reveal themselves in the physician's normal sphere of work. If he sought such information by direct questioning, he would probably be met by a bland denial of any egocentricity, unkindness, or volubility. Such characteristics are hardly those to which the average patient would be eager to lay claim; though a further reason might be the lack of insight with which these symptoms were associated.

To all this I believe we can add another explanation —a halo effect. Even if a patient has some insight into his failings (which, as a matter of fact, he usually euphemistically interprets and describes as a little irritability or impatience), or if they are brought to his notice by his friends or relatives (in any case an unlikely event) he will be reluctant to complain of them to the doctor who has helped him and removed him from an existence of misery and anxiety to show him promise of a full and happy life.

These, then, are some of the reasons why the early results of leucotomy were rather poor prognostic guides as to its ultimate usefulness and application. Moreover, the complacency, which not unnaturally developed from the apparently uncomplicated early successes, probably hindered any extensive inquiry into the social and civil aspects. But when these were adequately investigated many kinds of alteration of the personality were determined and analysed (Freeman and Watts 1950, Hutton 1947a and b, Knight 1943, Meyer and McLardy 1946, Partridge 1950, Rylander and Sjöqvist 1946, Rylander 1947a and b, Ström-Olsen 1945, Ström-Olsen and Tow 1949). Now Partridge (1950) says that every patient has deficits of some sort; though he rightly prefers to refer to them as trends rather than as fixed characteristics. It is important to pay particular attention to the patients' capacity for work and pleasure, their inner feelings, their judgment, and their acceptability to others.

IN THE HOME

Patients in their own homes are often found to be dirty and untidy in their dress and habits. It is easy to understand how such a thing might have been previously obscured by their being washed and made presentable by their relatives for the day they came to the clinic for their routine follow-up. Often at home they are found to be irritable or overbearing. One woman, previously in the depths of depression and inertia, would rant and rave for no cause at quite inoffensive members of the household. She would dust through the dining-room in the middle of a meal, and might insist on taking up the carpet when others wanted to settle down to listen to the wireless; all of which activities would be carried through in the face of all reasonable objection.

Many patients become obstinate and self-willed, and if not allowed to have their way become explosively aggressive. One, for example, was so euphoric and joyous, but at the same time so overbearing, that her family actually said, "Of course for *her* the operation has been a miracle; but *we* wish we had not got to live with her." One good lady always contrived to monopolise the conversation with irrelevant nonsense whenever visitors appeared in the house; while another would walk boldly in the middle of main roads, expecting all traffic to get out of her way.

Some retire very much into their own shell and either refuse, or do not want, or have not the initiative, to go out at all. One woman, preoperatively very active and adept at all the numerous activities to which a parson's wife must turn her hand, afterwards rarely did more than look at the morning paper. One husband complained that his wife neglected all household duties and was always out on the spree. She might condescend to a little cooking, but would throw the ingredients together with an abandon which had variable and unexpected results.

In others the symptoms may be more distressing or objectionable. One girl developed a postoperative hobby of writing me a regular stream of demanding and sometimes abusive letters, packed with the most descriptive neologisms. And there was, of course, the patient of Partridge whose flippantly amorous behaviour embarrassed even her husband. Though several became excessively conceited or just bluntly tactless, it was exceptional to find one who resorted to persistent lying.

I should state that Partridge has not placed nearly so much weight on some deficits as I have myself, though I think it fair to say that disagreement is largely one of incidence, and could be due to different types of material.

One could give numerous examples, but I will just add that, in general, some patients become unkind or inconsiderate, and occasionally cruel and callous; and some do, indeed, seem to develop a certain spiritual apathy, and a dwarfing of ethical standards. I do not mean that they steal or lie, for there has been an unexpected lack of obvious and overt manifestations of conventionally unacceptable conduct; but there is sometimes a disregard of what I would say are more significant things, such as the right and wrong way of treating a child, the kind and proper way of behaving towards invalids, or tolerance and understanding of the aged.

These conclusions can be expressed by saying that there is a discrepancy between the state of patients as assessed medically by established methods of clinical examination and their state as assessed socially, in the workshop, and at play. In other words, the operation has two effects—one may call them the therapeutic and the traumatic—and hence come the questions as to its ultimate usefulness or ethical justification. (Perhaps I should point out, in passing, that in any one patient the operation only produces one total set of changes.) In properly selected cases it may cure the illness; but in these—and of course in others—it damages important aspects of the person. For surely those aspects are important which determine the patient's social and cultural existence, his ability to work, his pleasures, his acceptability to his fellows, and, for all we know, his spiritual, as well as his emotional experience.

GAINS AND LOSSES

In a recent annotation (*Lancet* 1952) this matter was most accurately and pertinently discussed. After saying that "in many cases the state of the patient is otherwise so miserable and hopeless that few would question the wisdom of operating," the writer continues:

> "When, however, the operation is advised for relatively benign states of psychoneurosis, or for the relief of pain, it becomes necessary to examine very critically the balance between gain and loss. . . .
>
> "The 'cured' patient is likely to be emotionally blunted and may become friendless. The finer human relationships depend on a delicate balance of feeling which cannot survive the tactless remark, the thoughtless act, or the failure to show understanding. When are we therefore ethically justified in advising a procedure which, though it relieves the misery of neurosis or of pain, will also dull the patient's sense of responsibility, conscience, and feeling for others?"

Even so, the operation has already produced a vast mount of relief from chronic mental suffering. In a ertain proportion of disturbed and tense psychotics it s now, in my opinion, often the treatment of choice; nd in these cases I think it is necessary to make a arge incision. This will produce the undesirable comlications of which we are now aware; but in such opeless invalids surely we are justified, if not in ignoring hese complications, at least in regarding them as we lo the addiction to morphine which results in the heavily rugged case of cancer. I have felt that the deplorable reoperative state of many of these patients is often not ully realised by some critics of the operation.

It is in the relatively benign cases that we must veigh carefully the gains against the losses before dvising trauma to a healthy brain. Bearing in mind the operative mortality of 3–5%, the varying and often arge incidence of epilepsy, a number of deaths due to ater physical complications which we still do not fully understand, and the intellectual and personality changes —which may have significance in spheres other than medicine itself—I think we must be cautious in operating on the better type of patient.

The issues raised on the ethics and usefulness of the procedures would seem to lead to two essential questions for any one operation: Is it any good? Is it justifiable? With this in mind there should, while these empirical procedures remain a practical necessity, be two trends: (1) the gradual restriction of the original major incision to very ill patients where the therapeutic gain is obvious; and (2) the trial, and careful and *adequate* appraisal, of small localised ablations performed initially in skilled hands.

ACTION OF BELLADONNA ON GASTRIC MOTILITY IN MAN

W. FERGUSON ANDERSON
M.D. Glasg., M.R.C.P., F.R.F.P.S.
CONSULTANT PHYSICIAN, FORESTHALL HOSPITAL, GLASGOW; FORMERLY SENIOR ASSISTANT, MEDICAL UNIT, CARDIFF ROYAL INFIRMARY

DESPITE the widespread use of belladonna, the action of this drug on the human stomach has not been adequately investigated.

Textbooks agree that it controls excess motor activity —e.g., hyperperistalsis and pylorospasm—but only slightly decreases the volume of the gastric juice. Douthwaite (1947), working with *l*-hyoscyamine, the alkaloid to which the main effects of belladonna are attributed, concluded that belladonna does not affect the acidity of the stomach, but he observed radiologically much diminution in the gastric contractions. Schick (1910) had previously declared that the chief action of belladonna lay in overcoming pylorospasm. Croxon Deller (1948) stated that belladonna was of great value in relaxing spasm at the pylorus or at the site of peptic ulceration.

Anderson and Morris (1943) have shown that atropine sulphate has a biphasic effect on the pulse-rate and gastric motility. At first it slows the pulse-rate and stimulates the gastric contractions; and later it quickens the pulse-rate and stops stomach movements.

METHOD

This investigation was made on thirty-two people, of whom twenty-nine had no apparent abnormality of the gastro-intestinal tract, two had duodenal ulcers, and one had ulcerative colitis. The experiments were conducted in a quiet room, with the subject fasting and under continuous observation. The pulse-rate was recorded every 5 minutes for 20 minutes before, and for 1–3 hours after, the administration of belladonna. In two cases continuous electrocardiographic tracings were taken. The contractions of the fasting stomach were recorded by a modification of Carlson's balloon method (Anderson 1943).

Tincture of belladonna (*B.P.*) was given by mouth in doses ranging from 5 to 60 minims made up to 2 fluid oz. with water. To compare the effects of belladonna with those of atropine, 1 mg. of atropine sulphate was given orally in the same amount of water and, in another set of experiments, in a teaspoonful of 70% alcohol diluted to 2 fluid oz. with water. This latter method was used to ensure a solution of atropine similar in quality to the tincture used in the tincture of belladonna. As a control for these experiments, the approximate amount of alcohol in 60 minims of the tincture of belladonna—i.e., 60 minims of 70% alcohol—was given in 2 fluid oz. of water on eight occasions to seven people. Pulse-rate and gastric contractions were recorded as described above.

So far as gastric motility is concerned, it must be emphasised that, in both the controls and with belladonna, cold water given orally stops gastric contractions. This was first described by Carlson (1916) and confirmed by Anderson (1943). The inhibitory effect of 4 oz. of water usually lasts 10 minutes, and with 2 oz. of the mixture of alcohol, atropine, or belladonna gastric motility was commonly inhibited for 2–4 minutes. The only exception to this finding was in the presence of a duodenal ulcer; in such cases the usual inhibitory effect does not take place (Anderson 1943, Kay 1947).

In the recordings of gastric motility three phases were seen: active contractions, tonus rhythm, and relative quiescence. The active contractions were sharp spike-like waves lasting 30–40 seconds. Tonus rhythm was composed of regular flat-topped waves, each of which lasted 90 seconds. Relative quiescence was the nearest approach to complete rest found in the fasting stomach; it was characterised by undulating waves of low amplitude lasting about 2½ minutes.

Drugs may have varying effects on gastric motility according to conditions existing at the time of administration. If the stomach is showing active contractions, the drug may stop them, increase their frequency and/or amplitude, or leave them unaltered. The result of a single experiment is worthless because these periods of contractions are self-limiting, and, though normally lasting ½–1 hour, might be ending spontaneously at the time of administration of the drug. Therefore conclusions about the action of a drug depend on the repeated demonstration of a particular pattern of stomach movements.

RESULTS

Controls

With one exception, all the cases showed no alteration in pulse-rate after the administration of alcohol in water. In the one exception the pulse-rate slowed by 7 beats per minute immediately after the dose and returned to its previous level in 10 minutes.

In every case, after the inhibitory effect of the fluid administered had passed off, gastric motility remained unaltered for 23–37 minutes, and the pattern of the

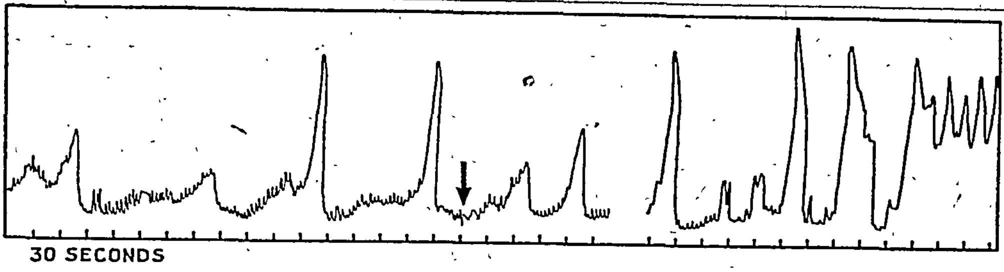

Fig. 1—Gastric motility in case 4 (table I): *arrow*, tincture of belladonna minims 5 given orally during active contractions. Increase in frequency and amplitude came on in 12 minutes and reached tetanic spasm in 20 minutes. The tracing has been condensed by omitting the middle part.

gastric movements never resembled that noted after belladonna or atropine.

Belladonna 5–15 Minims

Tincture of belladonna 5–15 minims was given by mouth on eight occasions to six people. The effects on gastric contractions and on the pulse-rate are shown in table I, and a typical result is illustrated in fig. 1. In every case the administration of belladonna was followed by slowing of the pulse-rate; this took place 5–10 minutes after the belladonna was given, and lasted for up to an hour. No increase in the pulse-rate was noted.

TABLE I—EFFECTS OF BELLADONNA ON PULSE-RATE AND GASTRIC CONTRACTIONS

–	Decrease of 3–5	Decrease in amplitude or in frequency
– –	,, 6–10	,, ,, and frequency
– – –	,, 11–20	Onset of relative quiescence

* Increase in frequency and amplitude occurred 33 minutes after administration.

In five out of seven occasions when active gastric contractions were present at the time of administration, contractions were increased in frequency and amplitude after 5 to 12 minutes. Once, when no active contractions were noted before the belladonna, contractions started 6 minutes after it was given. On two occasions the contractions continued unaltered. In no experiment did the belladonna inhibit gastric contractions, and there was always a close time-relation between the slowing of the heart and the increase in frequency and amplitude of gastric contractions.

After belladonna had been given, the greatest increase in gastric motility and the greatest slowing of the pulse-rate took place in 13–35 and 5–45 minutes respectively. People aged less than 40 showed more slowing of the pulse-rate than did those aged more than 40.

Belladonna 30 Minims

Tincture of belladonna 30 minims was given orally on six occasions to five people. In each case there was a preliminary slowing of the pulse-rate in 5–20 minutes, which lasted for at least 1 hour. In two cases, where the pulse-rate was recorded for a longer time, the rate increased by 4–7 beats a minute, and this took place 80 and 90 minutes after the belladonna had been given.

The effects on gastric motility were varied. In two cases, where the belladonna was given during a phase of relative quiescence, active contractions ensued in 6 minutes, and in a further two cases active contractions, already present, increased in frequency and/or amplitude. In the remaining two cases no alteration in the gastric motility was noted. In two of the above subjects, where an increase in gastric motility was first recorded, there was a later phase of relative quiescence, and the initial slowing of the pulse-rate was followed by a quickening when the decrease in gastric motility was noted.

In all the experiments increase in gastric motility and slowing of the pulse-rate were greatest 12–29 and 15–40 minutes respectively after the belladonna. Again the pulse-rate slowed more in the younger people.

Belladonna 45 Minims

Tincture of belladonna 45 minims was given orally to seven people, as shown in table I. In every case there was well-marked initial slowing of the pulse-rate in 5–10 minutes, which lasted 20–85 minutes. In two cases the pulse-rate remained slow for 80 and 85 minutes after the belladonna. In the remaining five cases this initial slowing was followed by a quickening, which took place in 21–40 minutes.

As regards gastric motility, in four cases active contractions already present were augmented in 5–20 minutes, and these times corresponded fairly closely to the onset of the slowing of the pulse-rate. In one case, when the belladonna was given during relative quiescence, active contractions started in 14 minutes. In three of the subjects showing an increase in gastric movements, as a second effect the active contractions abruptly diminished in frequency and amplitude and continued thus until the recording was stopped (fig. 2). This occurred at the same time as the pulse-rate quickened. In the remaining two cases an inhibitory effect was observed in 16 and 27 minutes after the belladonna. After belladonna had been given the maximum slowing of the pulse-rate took place in 10–50 minutes and the gastric contractions were greatest in 12–40 minutes.

TABLE II—TIME-RELATIONS OF CHANGES IN PULSE-RATE AND GASTRIC MOTILITY

Dose	No. of cases	Time of onset after dose (min.)				Time of maximum effect after dose (min.)		Maximum effect on pulse-rate (beats per min.)	
		Pulse-rate		Gastric motility		Pulse-rate	Increased gastric contractions		
		Slowing	Quickening	Increased	Diminished			Slowing	Quickening
Tincture of belladonna

30 minims	6	5–20	80–90	6–29	15–20	15–40	12–29	21	7
45 minims	7	5–10	20–40	5–20	16–54	10–50	12–40	14	31
60 minims	5	5–15	20–60	7–13	14–40	15–30	8–37	11	30
45 minims after previous administration of belladonna	4	5 (1 case)	20–50	8–26	9–54	15 (1 case)	24–26	4 (1 case)	28
Atropine 1 mg. in water	6	10–20	40–135	8–38	28–29	30–45	16–54	31	22
Atropine 1 mg. in alcohol ..	6	5–30	35–100 (no quickening in 3 cases)	14–33	10–65	20–65	16–54	17	30

Belladonna 60-Minims

The results found when 60 minims of the tincture of belladonna were given by mouth to five people are shown in table I. In every case there was a preliminary slowing of the pulse-rate 5–15 minutes after the belladonna, and this was followed by an increase in the rate 20–60 minutes after the belladonna. In one case no effect on gastric motility was observed, but in the other four there was a preliminary increase in the frequency and amplitude of active contractions 7–13 minutes after the belladonna. In one case, no inhibition was evident, but in the remaining three the gastric contractions stopped 19–40 minutes after the belladonna. A typical result is shown in fig. 3. Further, in these four cases (table I) there was a close time-relation between changes in the pulse-rate and changes in gastric activity.

Repeated Medication

It has been previously shown that a small dose of atropine has a parasympathomimetic action, increasing the frequency and amplitude of the gastric contractions and slowing the pulse-rate; it has also a sensitising effect whereby antiparasympathetic action is obtained from a second small dose (Anderson and Morris 1943). A single dose of 45 minims of the tincture of belladonna was given orally to fasting people after a week's continuous administration of 15 minims three times a day. In these experiments only one of the four persons investigated showed a preliminary slowing of the pulse-rate. It will be recalled that this slowing of the pulse-rate is a constant feature when a single dose of 45 minims is given without previous medication. The action on gastric motility varied, tending to be sedative at the time when the pulse-rate was most rapid. The preliminary phase of increased gastric motility was smaller than usual, and in every instance the pulse-rate was quickened as a second effect.

Atropine Sulphate

Atropine sulphate 1 mg. was given orally to compare the action of belladonna with that of atropine. The atropine was given dissolved in 2 fluid oz. of water and, to a separate group of people, in a teaspoonful of 70% alcohol. In this latter series water was added to 2 fluid oz. to compare the atropine more accurately with the tincture of belladonna. The amount of alcohol present was about equivalent to that in 60 minims of the tincture of belladonna.

When 1 mg. of atropine sulphate in 2 fluid oz. of water was given orally, all six people showed a preliminary slowing of the pulse-rate in 10–20 minutes. In five of the six the pulse-rate increased in 40–135 minutes after the administration of atropine. In one case the recording of gastric motility was unsuccessful, and in the other five the motility increased 8–38 minutes after atropine sulphate. In one of these cases, two phases of slowing of the pulse-rate were found, together with a corresponding alteration in the gastric motility. Initially, 12 minutes after atropine was given, the gastric contractions increased in frequency and amplitude and the pulse-rate slowed. The gastric contractions ceased, and at the end of this sedative phase the pulse-rate increased. Then, 44 minutes after administration of the atropine, the contractions began again, and in 58 minutes the pulse-rate slowed again. The contractions finally ceased 78 minutes after the atropine had been given, and at the same time the pulse-rate quickened. In a further case, after the initial increase in gastric motility, the contractions became less frequent 28 minutes after the atropine (table I).

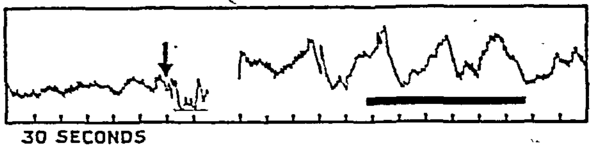

Fig. 3—Gastric motility in case 22 (table I): arrow, tincture of belladonna minims 60 given orally during active contractions. Increase in frequency and amplitude of contractions came on in 7 minutes and lasted 21 minutes. Black line shows time during which pulse-rate was slowed. The tracing has been condensed by omitting the middle part.

When 1 mg. of atropine sulphate dissolved in 1 fluid drachm of 70% alcohol, and diluted to 2 fluid oz. with water, was given to six people an initial slowing of the pulse-rate occurred in 5–30 minutes in every instance. In three of the six cases an increase occurred in 35–100 minutes, whereas in the remaining three people no such increase was recorded. In three of the five successful gastric recordings gastric motility increased in 14–33 minutes. This was followed in two cases by diminished gastric

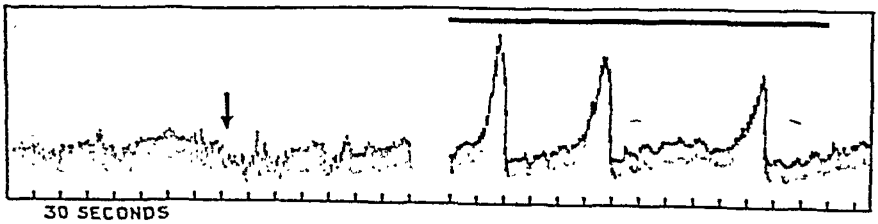

Fig. 2—Gastric motility in case 16 (table I): arrow, tincture of belladonna minims 45 given orally during very weak active contractions. In 5 minutes stronger contractions came on and remained of high amplitude for 25 minutes and then abruptly ceased. Black line shows time during which pulse-rate was slowed. This abbreviated tracing shows the last three contractions only.

activity in 50–57 minutes after the atropine. In one case no initial change in the motility was produced, but in 65 minutes contractions became less frequent, and in another case the frequency and amplitude of contractions decreased in 10 minutes and relative quiescence was achieved in 54 minutes.

Electrocardiography confirmed the changes in heart-rate following the administration of belladonna and atropine noted above. Electrocardiograms showed only findings associated with bradycardia and tachycardia.

DISCUSSION

Slowing of the pulse-rate and increased gastric motility quickly follow the oral administration of belladonna. Table II shows the times of the various actions, and it will be noted that, apart from a slightly slower onset of effect, atropine given orally seems to have the same action as belladonna. In the past belladonna has often been prescribed for its slower absorption, but no evidence in support of this contention has been obtained. With both atropine and belladonna the slowing and increase of pulse-rate occur at about the same times as the stimulation and cessation of gastric motility respectively.

Steinmann et al. (1948), investigating the effect of 'Bellafolin' (an alkaloid preparation of folia belladonnæ) on the circulation of healthy persons, found that the effect varied with the dose: a small dose slowed the pulse-rate, whereas larger doses increased it, usually with a preliminary phase of slowing. Goodman and Gilman (1941) describe the biphasic action of atropine on the pulse-rate; the temporary slowing with small doses they ascribed to the slight stimulant action of atropine on the medullary vagal centre. This slowing, they state, is rarely well marked or significant. Anderson and Morris (1943) have shown that parenteral atropine has a parasympathomimetic action, increasing the frequency and amplitude of active gastric contractions and slowing the pulse-rate. These doses have also a sensitising effect whereby an antiparasympathetic action is obtained from a second small dose. In large doses atropine inhibits the movements of the stomach and quickens the pulse-rate. With small doses of belladonna this slowing of the pulse-rate is the usual result and is accompanied by an increase in the frequency and amplitude of active gastric contractions. It is tempting to postulate that both these effects are due to central stimulation of the vagus. These effects are well marked, and it is therefore difficult to believe that they are of no clinical significance. Previous administration of belladonna has been shown to interfere with this central effect, the slowing of the pulse-rate being usually absent, and the initial increase in gastric motility being almost abolished.

From the present experiments it seems reasonable to use the pulse-rate as a guide to the action of belladonna on the stomach movements.

Belladonna must be given in a dose of at least 45 minims of the tincture if inhibition of the gastric contractions is desired from a single dose. Even with this dose this effect is by no means constant, and it may take as long as 40 minutes to appear. When repeated doses of belladonna are given they should be as large as the patient will tolerate, because only then will gastric motility be decreased. These repeated doses are much more likely than a single large dose to have an inhibitory effect.

It seems possible that the stimulating action of small doses of belladonna has some clinical use. The benefit obtained with belladonna in pyloric stenosis of infants and adults has never been explained. It is usual for substances which increase the motility of the stomach to relax the pyloric sphincter; and it may be that this stimulating effect on gastric movements initiates this usual pattern of motility—i.e., active peristalsis is associated with relaxation of the pyloric sphincter.

SUMMARY

Tincture of belladonna in small doses given by mouth has a parasympathomimetic action, slowing the pulse-rate and increasing the frequency and amplitude of active gastric contractions.

With larger doses, after a preliminary phase of slowing of the pulse-rate there is an increase in the rate. This biphasic effect can sometimes be demonstrated on the fasting contractions of the stomach, a short phase of increased movements being followed by the cessation of gastric contractions.

After preliminary medication with belladonna a large single dose does not produce the usual slowing of the pulse-rate, and the initial increase in gastric motility is less.

Electrocardiography after belladonna confirms these findings and gives tracings indistinguishable from those seen in simple tachycardia and bradycardia.

Given by mouth, atropine sulphate has the same action as when injected parenterally—i.e., it causes a slowing of pulse-rate followed by an increase, and an initial stimulation of gastric movements succeeded by diminution. These effects are produced rather more slowly than those produced by belladonna. It was thought that this action might be due to the alcohol content of the tincture of belladonna. Atropine was therefore given in an alcoholic solution about equivalent to the tincture, but no change in the speed of action of the atropine was observed.

I wish to thank Prof. Harold Scarborough for his advice and Dr. Myrddin Evans and Dr. A. G. Freeman for their helpful criticism.

ON THE TREATMENT OF ANOGENITAL PRURITUS

R. D. SWEET

M.B. Camb., M.R.C.P.

CONSULTANT DERMATOLOGIST, SOUTH DEVON AND EAST CORNWALL HOSPITAL, PLYMOUTH, TORBAY HOSPITAL, AND NEWTON ABBOT HOSPITAL

So much has been written recently on the psychogenic origin of pruritus ani and pruritus vulvæ that dermatologists and gynæcologists alike are not only becoming convinced that these difficult cases are the result of some past emotional disturbance but are also only too thankful to argue that, if there is a psychological cause, it must be dealt with before irritation can cease (e.g., Cormia 1951). Thus psychiatrists are reaping an embarrassing reward for the researches of their fellows, in spite of the fact that it has never been claimed that psychiatric treatment can necessarily cure all, or even a large proportion, of those who suffer from disorders which may have originated from mental trauma. Perhaps because anogenital pruritus is such a difficult and unrewarding condition to treat, or perhaps because most dermatologists and gynæcologists fight shy of becoming too deeply involved with the souls as well as with the bodies of their patients, our approach to the subject has become confused and an attempt should be made to understand it more clearly.

CAUSE AND EFFECT

A girl has a brutal and drunken father and is overfond of her mother. To escape from home she marries young, but sees much in her husband that reminds her of her father. She derives little satisfaction from sexual intercourse, becomes frigid, and, as time goes on, spends more and more time at home with her mother. Her mother dies, and by this time her husband is quite understandably losing interest in her. She becomes lonely and has no-one to comfort her. She begins to itch.

This facile and entirely fictitious history might easily be extracted from a woman of 30 with severe pruritus vulvæ which has been present for ten years. Here is our cause—the failure to establish a satisfactory marital relationship because of an unsatisfactory home life in childhood. Our logic, our very philosophy, makes us work backwards from the present state to its beginning ten years before, and there we find what we believe to be its origin. Yet this origin itself is a compound of cause and effect—the early environment and the reaction to marriage. Can we be sure that cause and origin are the same? Does the origination of a process, or its cause for that matter, determine its duration? If not, what does? Perhaps our hypothetical girl has a sister who also married, in which case we wonder if the sister's marriage was a success as our patient's was not; perhaps the sister's marriage also proved a failure, but we doubt if she too developed pruritus vulvæ. Our cause is becoming a little less definite, but our effect remains; our patient still sits before us complaining bitterly that the irritation is intolerable, that it is keeping her awake at night, that she "can't leave herself alone."

Let us suppose, however, that our patient's symptoms did originate as a direct result of her unhappy circumstances. All this was ten years ago. What is the relationship between cause and effect over this period? What has happened during the ten years? Why is she still itching? Mankind has proved itself the most adaptable of creatures, and it seems most unlikely that during the years there has been no change of circumstances, no rearrangement of personality, no compensation found other than itching. Can the origin also be the continuing cause, or has something else kept the irritation going? It is surely more reasonable to suggest that, whatever may have initiated the trouble, some more simple mechanism, common to other cases and to skin in other areas, has perpetuated it.

Let us turn now to some more material cases:

> A woman, an older woman, has pruritus vulvæ and is found to be a diabetic. Her diabetes is treated, and she passes no more sugar in her urine, but her irritation unexpectedly persists.
>
> A man has pruritus ani. He is found to have threadworms, and these are eradicated, but his irritation does not cease as was hoped.

There is one thing in common in these cases—a fairly long history, six months or more in each of them. It seems that, after a time, anogenital pruritus may become self-perpetuating, whether its original cause is still present or not; and so it becomes of equal importance to seek out and attack the continuing cause as well as the origin of the complaint.

PRESENT CONDITION

I have tried to show the relative unimportance of the origin of the irritation in these patients and to focus attention on them as they are when they present themselves for treatment after months or years of symptoms. Let us now examine our patient. The first complaint is itching, severe and continuous, and almost always worse at night. This leads directly to scratching by the patient, at first just in spasms and fairly well controlled, but later more and more uninhibited and unrestrained, especially in bed at night, until in the final and most common stage this scratching becomes a habit, an unconscious "spinal reflex," which continues during sleep until it becomes violent enough for the patient to wake himself up, though he seldom admits or even realises this, but says it is the irritation which wakes him. By this time the patient's sleep has usually become so interfered with that his life is becoming a misery, what self-control he had is lost, his work is suffering, and, as he often puts it, "his nerves are going to pieces." It is my impression, though it is hard to be certain, that it is only at this stage that he can be induced to go to the doctor, as by then he is at the end of his tether, and this may partly explain the usual long history.

Other factors must be considered before deciding on a rational form of treatment for anogenital pruritus, and most important among these is the attitude of the patient to his affliction. First there is often a strong sense of shame, of inadequacy, and a reluctance to expose themselves for examination, which may also help to explain the long period before advice is sought. Then there is very often the fear of infection (or malignancy) which often gets woven into a most complex but entirely fictitious history naming the time and place of the contagion. These sensations of fear and shame further add to the patient's discomfiture and, I am quite sure, often play just as important a part in the present psychological state as the now intangible happenings of long ago. The patient has in fact developed a neurosis as the result of his physical state, and here the words of Sargant (1951) are well worth quoting:

> "The presence of obvious functional components does not necessarily mean that they are the cause of the illness. One reason for attributing too many physical illnesses to psychological disorders may be that some people, when they get physical disorders, also become neurotic about them, whereas others do not. Those who become neurotic about their disability are the group most often seen by psychiatrists. The finding of neurotic traits may lead to the false conclusion that these are causal, whereas it may only indicate that those with tendencies to neurosis are the most likely persons to become neurotic about added physical disabilities."

PAST TREATMENT

The last factor I wish to consider is the failure of past treatment to relieve the irritation. If a doctor has been consulted, it is always demoralising for the patient if his treatment has failed. Also these people have usually tried out many applications themselves, often with disastrous results, though they may not realise it. For instance, a lady told me proudly that the best treatment she had found for her pruritus vulvæ was to paint herself with pure lysol. This, she assured me, entirely removed the irritating skin and so, though painful, cured her itching for the time being. And yet, what other rationale is there for vulvectomy in these cases? There is no doubt that, just as deeply as cause and effect are linked in our philosophy so are crime and punishment, and a shameful disease demands exorcism in many minds. This is very often seen in skin patients, who are not the least upset if some ointment violently irritates their lesions but, on the contrary, are delighted that "it is driving it out," as is shown by the profuse serous exudate so caused. Thus some patients with pruritus vulvæ or pruritus ani will take tremendous punishment under the impression that this is doing them good, and sometimes in telling their story it is quite clear that they are referring as much to their souls as to their bodies, and often confusing the one with the other. So to the trauma of scratching is not infrequently added the trauma of unsuitable medication, leading to further irritation and further scratching.

TREATMENT

We have discussed some remote causes, psychological and physical, and the continuing causes—namely, scratching, unsuitable medicaments, and the psychological results of long-continued and disabling irritation—and we should now be able to compose a logical scheme of treatment for these cases. The one factor of paramount importance is continual scratching, and this must be impressed on the patient first, last, and all the time. He or she must be told that the whole and only object of any treatment is simply to help to break the scratching habit—it is for the patient to do the rest. If there is no more scratching, the skin will *get better by itself*, as it surely will. From this homily on scratching it naturally follows that there is *no infection present to be feared*, and if there is anything to be ashamed of it is nothing more serious than being so foolish as to have gone on scratching for so long. Most patients will accept this explanation quite readily and often with obvious relief, but will reply with sudden and surprising candour that the trouble is that they cannot help scratching. They must then be told quite explicitly how it is proposed to help them. In the first place they must sleep well. They are unlikely to scratch very much in a deep sleep, and after a week or two of sleeping well their morale will be restored and their general health improved, and they will be much less troubled by any irritation they may still experience. The actual hypnotic chosen is not of great importance provided it achieves its object. It is my practice to use 'Sodium amytal' gr. 3 or gr. 6, and I believe that this type of barbiturate is preferable to phenobarbitone, which leaves the patient with more of a "hangover" next day.

Though ample sedation at night is probably the most important consideration in managing these cases, local applications are of considerable help, and some form of tar preparation is still the most useful. The following paste, though messy, is a powerful antipruritic and forms part of my routine treatment:

Crude coal tar	5%
Zinc oxide	5%
Starch	45%
Soft paraffin	45%

This is a greenish-black paste and is applied at night. Since it will otherwise make a mess of the bed-clothes, it is easy to induce patients to wear a thin pair of pants under their night clothes which makes scratching more difficult, and it is easy for them to tell by their blackened fingers in the morning if they had lapsed during the night and been scratching in spite of everything.

In the morning they are instructed to clean themselves thoroughly with cetrimide 1% and, in the cases of pruritus ani, to do so after they have had their bowels opened. This latter instruction ensures a good standard of hygiene and encourages attention to the bowels in those liable to be constipated, and who consequently suffer added discomfort from the passage of hard stools. Then again the knowledge that they are using a good "skin antiseptic" helps to dispel any lingering doubts about infection in the less believing patients, and makes it unnecessary for them to fall back on the secretive use of more irritating applications.

During the day, when the irritation is less and there is less opportunity or incentive for scratching, some bland and clean cream is applied. Ung. aquosum *B.P.* and 'Anthisan' cream are equally effective.

Finally, to guard against the lapses liable to occur early in treatment, the patient must be instructed to keep the finger-nails cut as short as possible.

Many applications containing local anæsthetics have been recommended in the past, and perhaps anthisan is useful because it has a mild local anæsthetic action. Preparations containing benzocaine are dangerous if used for any length of time, because some people become sensitised to this with disastrous results. As a sole approach to treatment *local anæsthetic ointments* are remarkably unsuccessful.

By far the greater number of cases of anogenital pruritus have very little to show in the way of visible changes, and it is probably this as much as anything that encourages the psychological approach so much favoured today. In many cases the skin looks normal, and in many more there is only a little lichenification of the perianal or vulval skin. If the scrotum is affected there is usually a definite thickened plaque, and such cases are usually more resistant to treatment but are fortunately less common. In any of the above, excoriation from scratching may be seen and occasionally some local œdema, especially of the labia majora. All may be treated with the routine tar paste. A few patients, especially those who are fat, have intertriginous lesions in the groins, and then it is advisable to begin with something more bland—e.g., calamine liniment—to settle the intertrigo before going on to the full routine, and it is often a help to put such patients to bed in hospital for a few days. Their general handling, however, is the same.

There is one type of patient, fortunately rare, in which the treatment outlined above is liable to fail, and that is the one who manifestly enjoys scratching and obtains an erotic satisfaction from it that is barely if at all concealed. This is commoner in the male with pruritus ani. There is a small group, usually in their twenties, who approach one with none of the diffidence to be anticipated in those suffering from such a complaint, and who have the disconcerting habit of dropping their trousers more quickly than expected and of thrusting their posteriors up at one. Their hygiene is usually not of the highest. The anal sphincter often seems to be deeply depressed at the bottom of a "funnel" between the buttocks. The skin around is invariably normal. They seldom complain much of irritation, except inasmuch as they find it embarrassing socially to be seen scratching themselves. Diagnosis is important from the doctor's point of view to save him wasting his time by attempting to treat such cases, and possibly to help him to understand why some of the more barbarous treatments of the past were ever devised.

RADIOTHERAPY

Radiotherapy is a most useful weapon in countering anogenital pruritus, but *it should not be used alone*; nor in my opinion should it be used when the patient is first seen. The mode of action of X rays in countering skin irritation is not understood, but there is no doubt that, in small amounts, they do depress or abolish itching *for a short time*. We are considering the treatment of a chronic condition, perpetuated by constant rubbing and scratching, and it is worse than foolish to offer a temporary alleviation of symptoms without making use of this period to help break the scratching habit, or without giving the patient something *to use* to help stop *scratching* when the irritation returns, as it invariably does a few weeks after the last treatment.

X rays must only be given as a part of the general management of the case, and for this reason, if for no other, the dosage and timing must be under complete control of the dermatologist. They are *only* needed in cases in which the treatment outlined above has failed to enable the patient to stop scratching, and once again it must be clearly explained to the patient that X-ray treatment will not cure the irritation, but it will give a period of relief which must be taken advantage of, as only a certain amount of X rays can be given without danger. He or she must be warned at the onset that after a few weeks there will be some return of the irritation, and that this will be the testing-time. *If scratching* starts again, the irritation will persist and get worse again, but if not it will rapidly fade away. With the patient understanding the object and limitations of the treatment, *X rays will often* prove the decisive factor in coping with these cases. A course of 3 or 4 exposures once a week of 75 or 100 r is adequate, and there is little or no advantage to be gained from larger doses.

TREATMENT OF COEXISTING CONDITIONS

Hæmorrhoids.—If we consider what common conditions pruritus ani and piles are, it is almost surprising that they are not found together more often. Patients with anal irritation often speak of their "piles" as a convenient excuse for their itching, and when they are examined there are none to be seen. If hæmorrhoids are present they should be treated on their merits, but not for the sake of any accompanying pruritus.

Fissures and Skin Tags.—Skin tags are of no significance and should not be allowed to become an excuse for surgical interference. Fissures are usually the result of previous lichenification. The thickened and hardened skin often cracks, especially immediately behind the anus, and these cracks are often painful. There is unfortunately little that can be done for these beyond attention to the condition as a whole. Excision and cautery are not recommended.

Vaginal Discharge.—Anything the gynæcologist can do to lessen or abolish vaginal discharge is of great help, because constant moisture of the over-sensitive skin of the labia tends to increase and perpetuate the irritation. Until the discharge can be controlled, such patients are better with a paste during the day as well as at night, because this gives some "waterproofing" to the affected areas. Ordinary Lassar's paste is as good as anything.

Leukoplakia Vulvæ.—I do not intend to discuss the treatment or diagnosis of this condition. Areas of leukoplakia are, however, found in some cases of pruritus vulvæ and must be recognised because of their liability to malignant change. The pain and irritation of these patients can usually be lessened considerably and sometimes abolished: but the routine of treatment described above should always be given, though X rays are better withheld. It seems reasonable to suggest that the less the leukoplakia areas are subjected to the mechanical trauma of scratching, the less is the likelihood of malignancy.

Lichen Sclerosus et Atrophicus of Vulva and Anus.—It is curious that this condition, which is usually without symptoms when it occurs elsewhere on the body, should cause irritation when it involves the anogenital area. There is unfortunately no known successful treatment for it, but once again elimination of scratching is of great help.

Psoriasis and Lichen Planus.—These two diseases may be responsible for irritating lesions in the groins and perineum. Lichen planus may produce white patches on the mucosal surfaces of the labia which may be mistaken for leucoplakia. Flexural psoriasis may closely resemble intertrigo. Treatment in both conditions must be largely symptomatic, and the principles mentioned above will be found useful, but the prognosis for recovery is that of the appropriate disease.

Diabetes and *threadworms* must be treated if present.

PSYCHIATRY

I do not propose to discuss the merits of psychiatry or the psychiatric methods to be adopted, for I am unqualified to do so. I merely wish to set psychiatry in its proper perspective and to point out that alone, and in detachment from other forms of treatment, it is as unlikely to succeed as is radiotherapy alone.

The state of mind of patients with severe and long-standing anogenital pruritus has already been discussed, as has the importance of restoring sleep, removing fears of infection, and explaining the nature of the complaint, so as to give them some insight and enable them to help themselves and be helped. It often happens that these patients tell of periods of stress at the time of onset of their pruritus or during its course, and they often wonder themselves if this stress played any part in the initiation or perpetuation of their itching. The following case serves as a good illustration:

An unmarried nurse, aged 55, complained of very severe irritation of her groins and vulval and anal regions, which had been going on for four years and getting worse all the time. For the last six years she had been nursing her sister, who was apparently mad and extremely difficult to live with. At last, six months ago, she had agreed to lay down her burden and allow the sister to be certified insane, a course she had strenuously opposed previously, insisting on assuming full responsibility for her. Soon after her sister departed to an institution the patient's pruritus became worse than ever. She was convinced she had "caught a germ" and, though at last free to do so, she feared to resume her nursing career in case she "passed it on to someone."

On examination she showed the severest lichenification of the groins, vulva, and anal cleft that I have ever seen. This patient had evidently had a very grim time looking after her sister, and I have very little doubt that she went through a period of acute misery before and after deciding to allow her to be removed to a mental hospital. It is quite possible that the feelings of guilt at quitting the job she had tackled for so long coincided with the acute exacerbation of her symptoms after the sister's departure. However, the above-mentioned routine of treatment, together with three weekly X-ray treatments of 100 r led to her losing all her irritation in from six weeks to two months, and she has had no relapse in the year that has followed.

Such patients are relatively common, but the coexistence of worry and pruritus does not necessarily imply cause and effect. The two interact on each other, but abolishing the worry will no more cure the pruritus than abolishing the pruritus will cure the worry, though it often helps considerably. It is not the worry, "the nerves," that produce the lichenification but the finger-nails.

In such patients psychiatry is seldom either necessary or desirable. The patient should be able to control his scratching himself, if helped as I have described, and it is a mistake to infer that he needs extra help; in fact it is tantamount to saying that the condition is beyond his control and so offering a cloak to hide his weakness.

The indication for psychotherapy is now plain—it is simply the utter incapacity of the patient to stop scratching.

CASES AND RESULTS

About 50 patients have now been treated along these lines in the last eighteen months with remarkably few failures or recurrences so far as is known, but only 32 have been followed up personally for six months or more, and only these will be briefly discussed. These patients are entirely unselected except inasmuch as they were all seen in the outpatient department of a general hospital at the request of their general practitioners, whose treatment had not succeeded in relieving their irritation. No case of any specific condition—e.g., psoriasis and lichen sclerosus—is included, but several patients had some complicating intertrigo. 14 were males, and 5 in addition to pruritus ani had irritation extending forwards in the perineum to the base of the scrotum; 18 were females, of whom 16 had pruritus vulvæ, and 8 of these had anal irritation also.

Of these patients 20 (10 male and 10 female) were aged 40–60 when first seen, 5 were aged less than 40, and 7 more than 60. The average duration of symptoms for the males was 3·3 years and for the females 4·8 years, but these figures do not mean very much, because the histories varied from 4 months to 20 years. 2 of the female cases had begun as diabetic vulvitis six months and a year before, and in each case the diabetes had been well controlled for several months and there was no apparent abnormality of the irritating skin. One man was reputed to have had threadworms eighteen months before and had been treated; no threadworms were found when he came to hospital.

All of these cases were improved with treatment, and 28 of the patients lost all their irritation in two months or less. In these 28 radiotherapy was used three times only. There has been no recurrence in any of these cases over a period of at least six months. 3 of the remaining patients have improved greatly but have occasional bouts of irritation and for this reason keep attending hospital, mainly for encouragement. All have been put back on the full routine of treatment from time to time and have settled down again. 2 have had a course of X-ray therapy. The remaining patient has only improved slightly:

She is now aged 36, and her pruritus vulvæ began when she was 16. It got much worse immediately after her marriage at the age of 25. Three years later, because there was a little vaginal discharge, a hysterectomy was done at another hospital, apparently in the hope that this might help her irritation. She had no children. As might be expected, she then became much worse and has been having treatment unsuccessfully ever since. There was gross œdema of the left labium majus, presumably due to lymphœdema following the repeated infection of fissures in the lichenified skin. There were numerous boils in the vicinity. She was admitted and put on the usual routine. The boils cleared up quickly simply with repeated cleaning with cetrimide, and there was fairly rapid improvement at first, but she could not stop scratching, especially at night. Increasing doses of sodium amytal up to gr. 12 were given at night, but she was repeatedly seen by the night staff scratching in her sleep. Unfiltered X rays 300 r were given in divided doses without helping her in the least. After discharge from hospital her improvement was maintained for a while, but she could not control her scratching, on her own admission, and she was referred to Dr. J. Gilroy for psychotherapy. Dr. Gilroy confirmed the existence of a sexual neurosis but does not hold out very much hope of success, because of the chronicity of the psychiatric as well as the physical condition. This treatment has not yet begun.

This case has been described in some detail because I had the opportunity of observing her closely, and though she has proved the only failure so far she has confirmed the concept that scratching is the continuing cause.

COMMENTS

The results obtained with this routine of treatment have been most encouraging, and so far there have been few relapses, because the patients understand, to their own satisfaction, the nature of their trouble, and know what to do about it if there is any mild return of their irritation. It will be appreciated that I am considering pruritus ani and pruritus vulvæ simply as instances of lichen simplex chronicus occurring in special areas, and it is probably only because the type of sensation arising from the anogenital area differs in quality from that of the rest of the skin that irritation there is more distressing than that from patches of lichen simplex elsewhere on the body. It therefore seems unnecessary to endow irritation from this part of the body-surface with a greater significance of psychiatric disturbance than when it occurs elsewhere. We are all familiar with the picture of the old sow solemnly scratching her back against a post and obviously deriving considerable pleasure from doing so. She would not dream of complaining to her doctor about her beloved itch, but might do so vehemently to the farmer if he removed the post. It is also a common sight on the part of Dartmoor where I live to see wild ponies scratching their nethermost regions. The most favoured method is to use the wire guy ropes supporting telegraph poles. The tail is looped over the wire and the hind quarters are pressed against it and the animal will rub away, often for a long time. Such an animal may become separated temporarily from its herd, and I have even heard it said that "scratchers" may lose condition because they do not take off sufficient time to feed. I feel, however, that it would hardly be acceptable to postulate that the lonely pony, pining for its strayed companions, sought consolation in scratching its backside. We are now back where we started—which is the cause and which the effect? Perhaps we do not know, but the pony, and the patient, are still scratching.

SUMMARY

The origins of anogenital pruritus are discussed and the reasons for its persistence. Scratching is the continuing cause.

The state of the patient, both mental and physical, is described, and from this is deduced a rational form of treatment.

The relative usefulness of X rays and psychiatry is discussed, together with the indications for using them.

Anogenital pruritus is usually only a variant of lichen simplex. It is perpetuated by scratching and not by whatever initiated the scratching. The precipitating cause has usually long since ceased to operate.

I wish to thank Dr. H. J. Wallace for his encouragement and kindly criticism in the preparation of this paper.

INCIDENCE OF ANTIBIOTIC-RESISTANT STAPHYLOCOCCI IN A HOSPITAL

PHYLLIS M. ROUNTREE
D.Sc. Melb., Dip. Bact.

EDGAR F. THOMSON
M.B. N.Z., F.R.A.C.P.

From the Fairfax Institute of Pathology, Royal Prince Alfred Hospital, Sydney, Australia

In previous papers (Rountree and Thomson 1949, Rountree et al. 1951) we reported the incidence of penicillin-resistant strains of *Staphylococcus pyogenes* in a general hospital, and the subsequent emergence of strains also resistant to streptomycin. Here we record the incidence of such strains during the thirteen months from Jan. 1, 1951, to Feb. 1, 1952. In addition we record the incidence of strains resistant to aureomycin, terramycin, and chloramphenicol, since these antibiotics became freely available during this period. Observations on the nasal carrier-rate in the staff are also included, and their significance is discussed.

The laboratory methods used are similar to those previously described, with the addition that tests for sensitivity to aureomycin, terramycin, and chloramphenicol were made with filter-paper discs impregnated with solutions of these substances 5 mg. per ml.

The monthly incidence of antibiotic-resistant strains isolated from 915 inpatients between Jan. 1, 1951, and Feb. 1, 1952, is shown in table 1 together with the figures for 157 outpatients' strains isolated in the same period.

RESISTANCE TO PENICILLIN

Of the inpatients' strains 592 (64·7%) were penicillin-resistant. In comparison with the figure obtained during the period April, 1949, to March, 1950, which was 53·4% of 603 strains, there was an increase of 11·3%. This is statistically significant ($\chi^2=8{\cdot}15$, $P<0{\cdot}01$). The frequency distribution of phage-types among these strains is discussed below in connection with the carrier state of the staff. There was also an increase in the incidence of resistant strains from outpatients, the incidence rising from 24·6 to 36·3%.

RESISTANCE TO STREPTOMYCIN

All the strains resistant to streptomycin were also resistant to penicillin. The monthly incidence of these strains in the inpatients fluctuated from 18·3 to 33·8%, with a mean value of 27·6%. This is about the

TABLE I—INCIDENCE OF ANTIBIOTIC-RESISTANT STRAINS OF *Staph. pyogenes* ISOLATED FROM OUTPATIENTS AND INPATIENTS BETWEEN JAN. 1, 1951, AND FEB. 1, 1952

	No. of patients	No. yielding strains resistant to			
		Penicillin	Streptomycin	Aureomycin and terramycin	Chloramphenicol
Outpatients	157	57 (*36·3%*)	17 (*10·8%*)	2 (*1·3%*)	—
Inpatients					
Jan., 1951	63	40 (*63·5%*)	22 (*34·9%*)	..	..

March ,,	70	41 (*58·5%*)	23 (*32·8%*)	..	..
April ,,	83	49 (*59·0%*)	16 (*19·3%*)	1	..
May ,,	77	45 (*58·4%*)	25 (*32·4%*)	2	..
June ,,	57	34 (*59·7%*)	13 (*22·8%*)	2	..
July ,,	51	37 (*72·5%*)	13 (*25·5%*)	1	1
Aug. ,,	86	59 (*68·6%*)	18 (*20·9%*)	8 (*9·3%*)	1
Sept. ,,	82	48 (*58·5%*)	15 (*18·3%*)	9 (*11·0%*)	1
Oct. ,,	66	44 (*66·6%*)	22 (*33·3%*)	11 (*16·6%*)	2
Nov. ,,	78	57 (*73·1%*)	22 (*28·2%*)	14 (*18·0%*)	1
Dec. ,,	62	42 (*67·7%*)	21 (*33·8%*)	12 (*19·0%*)	1
Jan., 1952	72	48 (*66·6%*)	24 (*33·3%*)	12 (*16·6%*)	4
Total	915	592 (*64·7%*)	253 (*27·6%*)	72 (*7·9%*)	11

same as that found in the period December, 1949, to March, 1950. There is reason to believe that most of these strains were the result of cross-infection in the hospital wards. Of the 157 outpatients' strains 17 (10·8%) were streptomycin-resistant. Most of these were obtained from varicose ulcers treated with local streptomycin.

RESISTANCE TO AUREOMYCIN AND TERRAMYCIN

These two antibiotics are considered together because it has been found that every strain resistant to one of them has also been resistant to the other.

The first resistant strain was isolated in April, 1951. Thereafter there were 2, 2, and 1 strains isolated in May, June, and July respectively. In August 8 strains were isolated, and in December 12 of 62 strains (19%) were resistant.

There are two points of interest about these strains—their sensitivity to other antibiotics, and their origin.

Sensitivity to Other Antibiotics

The sensitivity records show that 86 cultures were examined from the 72 patients yielding these strains with the following results:

	No.
Resistant to penicillin	84 (*97·7%*)
Resistant to penicillin and streptomycin	57 (*66·3%*)
Resistant to penicillin, streptomycin, and chloramphenicol	11 (*12·8%*)
Sensitive to penicillin, streptomycin, and chloramphenicol	2 (*2·3%*)

With the 2 exceptions, which were cultures from a patient treated with aureomycin for a staphylococcal skin infection, all the strains were resistant to penicillin, 57 (66·3%) were resistant to both streptomycin and penicillin, and 11 (12·8%) were resistant to all five antibiotics.

Origin

To ascertain whether the resistant strains had arisen as a result of conversion during therapy or were due to cross-infection, the case-records of 61 of the 72 patients were examined. The sources of the strains were as follows:

Infected surgical wounds	21
Infected burns	2
Infected ulcers	7
Urine	17
Sputum	8
Miscellaneous skin infections	6

Seven strains were isolated from urine showing no cellular evidence of infection and were considered to have been contaminants introduced in the ward after the specimens had been voided. All came from one ward, in which there had been considerable cross-infection. Of the remaining 54 cases none could be regarded as having been infected outside the hospital:

In 6 cases there was clear-cut evidence of conversion to resistance during therapy; 4 of these patients had received aureomycin and 2 terramycin. In all 6 the strain was identical in phage-type with that previously isolated as a sensitive strain. 4 strains came from infected surgical wounds, 1 from a case of osteomyelitis, and 1 from a chronic ulceration of the leg. 3 of these strains were isolated in April, May, and June.

There were 33 patients who had received no aureomycin or terramycin therapy, and these may be regarded as certainly cross-infected in hospital.

In the remaining 15 patients the data available were insufficient for us to make a definite decision on the origin of their strains. They had received aureomycin or terramycin therapy before the strains were isolated, but no sensitive strain had been isolated before the resistant one. In 10 of them the case-histories suggested that the strains were due to cross-infections.

In the early stages of the investigation phage-typing was only partially useful in identifying the strains, since many of them were apparently insensitive to the typing phages. Those in which conversion to antibiotic resistance had occurred were, however, identifiable, 3 belonging to type 47, and 1 each to types 7/47, 47C, and 31B. It was later found that most of the non-typable strains were only partially phage-resistant, and when tested with phages they proved to be type 47. Of 17 cultures all were thus identified as type 47. 30 of the cultures had been discarded without being tested with the undiluted phages, but in view of the later results probably most of these also belonged to type 47.

RESISTANCE TO CHLORAMPHENICOL

Only 11 strains were resistant to chloramphenicol. All were in addition resistant to the other four antibiotics. In 3 there was evidence of conversion to resistance during chloramphenicol therapy. Of the 11 resistant strains, 4 were isolated in January, 1952, and their incidence may be expected to increase in future months.

NASAL CARRIER-RATES OF ANTIBIOTIC-RESISTANT STRAINS IN HOSPITAL STAFF

In a previous paper (Rountree and Thomson 1949) it was shown that many of the hospital staff (nurses and doctors) were nasal carriers of strains similar to those isolated from patients cross-infected in hospital, and that certain penicillin-resistant phage-types were the predominant staphylococci in the hospital environment. It was later found (Rountree and Barbour 1951) that nasal carriage of these hospital strains was established in new nursing trainees within a few weeks of their entering the hospital wards, particularly if they were non-carriers on entry. Whether nasal carriers among the staff constitute a reservoir of infection for the patients or are merely infected from the same source as the patients—e.g., contaminated dressings, bed-clothes, and dust—the distribution in the staff of antibiotic-resistant strains and of the phage-types of these strains should be similar to that in the cross-infected patients.

Accordingly in February, 1952, we swabbed the noses of 200 of the nurses and doctors to find out what proportion were now carrying antibiotic-resistant strains, and what was the distribution of antibiotic resistance and phage-types among such carriers.

109 (54·5%) of the staff were nasal carriers of *Staph. pyogenes*, a carrier-rate similar to that found on other occasions. The following is the distribution of antibiotic resistance among these 109 strains:

	No.
Resistant to penicillin	88 (*80·7%*)
Resistant to penicillin and streptomycin	51 (*46·8%*)
Resistant to penicillin, streptomycin, aureomycin, and terramycin	17 (*15·6%*)
Resistant to penicillin, streptomycin, aureomycin, terramycin, and chloramphenicol	3 (*2·7%*)
Sensitive to penicillin, streptomycin, aureomycin, terramycin, and chloramphenicol	21 (*19·2%*)

Only 21 of the people swabbed were carrying penicillin-sensitive strains, and it is significant that 10 of these 21 were first-year trainee nurses who had been in the hospital for only a short time. The remainder (80·7%) were carrying penicillin-resistant strains. More than half these strains were also streptomycin-resistant. Strains also resistant to aureomycin and terramycin were obtained from 17 persons, and all were of type 47. In addition, 3 nurses were carrying strains resistant to all five antibiotics; these also were of type 47. Comparison of this distribution of resistant strains among the nasal carriers with that found in the patients in January, 1952, shows a reasonably close correspondence between the two sets of figures. The incidence of penicillin-resistant and of penicillin-and-streptomycin-resistant strains is lower in the patients than in the staff (66·6% compared with 80·7%, and 33·3% compared with 46·8% respectively). However, the patients' over-all percentages will include strains present when the patients were admitted to hospital; since the majority of these will be antibiotic-sensitive, the incidence of antibiotic-resistant strains calculated as percentages of the total will be lowered.

The two series of strains may be compared with reference to the phage-types they comprise. This information is set out in table II. In compiling the table, strains have in some cases been grouped into related phage patterns rather than differentiated on small variations in pattern. For example, all strains lysed by one or more of the phages 3A, 3B, 3C, and 51 have been grouped together, and within the groups denoted as 7/47/31B and 29/31/52 there are strains of various patterns. For the purposes of comparison, however, this arrangement is a convenient one.

There is close correspondence between the phage patterns of the strains of the two series, all patterns, with the exception of 6/47, being present in both groups. Correspondence between the frequency distributions, on the other hand, is less close. Since we are comparing a series of strains obtained from patients over a period of thirteen months with that obtained in a survey lasting two weeks at the end of the thirteen-month period, and since we know that these frequency distributions are dynamic rather than static, very close correspondence in actual percentages is not to be expected. There is also one obvious source of error in the figures for the patients' strains; included in the "not-typable" strains are a number of the aureomycin-terramycin-resistant strains isolated early in the investigation, which in the light of later findings may reasonably be considered to have been type 47. When all these factors are taken into consideration, the conclusion that the frequency distribution of strains among the nasal carriers of the staff reflects that found in the patients' lesions is justifiable.

DISCUSSION

Claims have been made that one of the advantages of aureomycin is that resistance to it is rarely developed. We found, however, that, after aureomycin therapy a number of strains resistant to *Staph. pyogenes* appeared in lesions. These strains were of the same phage-type as the sensitive organisms previously present in the lesions, and we conclude that resistant variants were selected as the result of the therapy. Moreover, such strains always became resistant also to terramycin. There were also 2 cases in which resistance to aureomycin and terramycin followed local terramycin therapy. From these observations it follows that if a staphylococcal infection fails to respond to aureomycin therapy it is useless to treat it with terramycin, and vice versa. Herrell et al. (1950) have already reported this linked resistance in strains made resistant in vitro.

TABLE II—PHAGE PATTERNS OF PENICILLIN-RESISTANT STRAINS OF *Staph. pyogenes* ISOLATED FROM PATIENTS' LESIONS AND FROM NOSES OF THE HOSPITAL STAFF

Phage pattern	Patients' strains	Staff strains
3A/3B/3C/51 ..	13 (*2·2%*)	1 (*1·2%*)
6/47	25 (*4·2%*)	..
6/7/47	17 (*2·9%*)	1 (*1·2%*)
7/47/31B	113 (*19·1%*)	14 (*15·9%*)
29/31/52	42 (*7·1%*)	5 (*5·7%*)
31B	92 (*15·6%*)	9 (*10·2%*)
42F	18 (*3·1%*)	4 (*4·5%*)
47	131 (*22·1%*)	35 (*39·7%*)
47C/47D	20 (*3·4%*)	5 (*5·7%*)
Not typable ..	112 (*18·8%*)	13 (*14·7%*)
Other types ..	9 (*1·5%*)	1 (*1·2%*)
Total	592	88

Chloramphenicol resistance following therapy can also occur. Among the 11 cases yielding strains resistant to all five antibiotics, there were 3 with clear-cut evidence of such a change. In 1 of these, the original infecting strain was resistant only to penicillin; but after therapy with aureomycin, streptomycin, and chloramphenicol it became resistant to all five antibiotics.

The emergence of the aureomycin-terramycin-resistant strains followed a course similar to that of the streptomycin-resistant strains in 1949. In the first few months following the introduction of the new antibiotics an occasional strain appeared after therapy with the antibiotic in question and was due to conversion to resistance. After a period of some months there was a sudden increase in the incidence of the resistant strains, and the majority of these were the result of cross-infection. These cross-infections apparently occur when the new strains have become well established in the hospital environment, probably both in the bed-clothes and dust of the wards and in the noses of the nurses and doctors.

An interesting point emerged on re-examining the results of the previous investigation of the first-year nursing trainees (Rountree and Barbour 1951). The first group of these nurses entered the wards in August, 1949, when there was little cross-infection with the penicillin-streptomycin-resistant strains, and only 1 out of 15 penicillin-resistant strains acquired by these nurses was streptomycin-resistant. The next group entered the wards six weeks later when cross-infection with the penicillin-streptomycin-resistant strains was occurring, and among this group all 7 penicillin-resistant strains acquired were also streptomycin-resistant, suggesting that in the six weeks' interim the new strains had become well disseminated in the wards.

The longer the nurse or doctor stays in the hospital, the more likely is he or she to become a nasal carrier of the hospital strains of *Staph. pyogenes*. In the three years that have elapsed since our first survey of nasal carrier-rates in the staff there has been a significant increase in the incidence of penicillin-resistant carriers, which now represent 8 in every 10 carriers compared with 6 in every 10 in the previous survey. Furthermore, half the carriers of penicillin-sensitive strains found in the present series were newcomers to the staff.

That the strains present in the hospital are constantly changing is shown by the differences between the incidences of phage-types and of antibiotic-resistant strains found in the patients and staff in the two surveys. In 1948–49 the majority of the penicillin-resistant strains belonged to one particular type, 31B. In the latter part of 1949, penicillin-streptomycin strains of types 47, 47/31B, and 31B appeared. Although type 31B is still found in both staff and cross-infected patients its incidence is now much lower and strains falling into patterns of 7/47/31B and 47 are now the predominant organisms in both groups of people Furthermore, concomitantly with the increased incidence of aureomycin-terramycin-chloramphenicol-resistant strains of type 47, we find these particular strains also among the staff nasal carriers.

Of the staff swabbed on previous occasions, 25 were included in the 200 examined in the present survey. In only 4 of these is their nasal carrier state the same as it was eighteen months to three years ago. 3 have been non-carriers on all occasions and 1 is still carrying the same strain as that isolated three years ago. The remainder are carrying strains different from those previously isolated.

The question whether the staff or the ward and theatre environment is directly responsible for the infection of patients seems to be unanswerable. Indeed, one is tempted to ask whether it is not redundant. Clearly, both routes of infection are practicable, and it will depend on particular circumstances which one operates. In our series of cases there was evidence of infection of wounds occurring in the theatres, and one nasal carrier of the penicillin-streptomycin-aureomycin-terramycin-resistant strain was found among the theatre sisters. There were also a number of infections which had obviously occurred in the hospital wards.

Finally, the emergence of strains resistant to all antibiotics at present available cannot be regarded without apprehension. In the present series there were 3 cases in which an antibiotic-resistant staphylococcal pneumonia was superimposed on other clinical conditions. Of these cases 2 had a fatal termination to which the pneumonia contributed.

It should, however, be emphasised that these antibiotic-resistant staphylococci appear to be confined to hospital environments. In a survey of blood donors carried out in April, 1951 (Rountree 1951), only 7 of 97 nasal carriers were carrying penicillin-resistant strains and no streptomycin-resistant strains were found. This was a similar incidence to that found in 1949. Similarly, Anderson (1951) reported that 100 strains of *Staph. aureus* isolated from lesions in casualty patients at their first attendance at the hospital were aureomycin-sensitive. It is only in the hospital environment that conditions obtain which permit the selection of the resistant variants and their subsequent spread to large numbers of people.

SUMMARY

Of 915 strains of *Staph. pyogenes* isolated from inpatients between Jan. 1, 1951, and Feb. 1, 1952, 592 (64·7%) were resistant to penicillin, 253 (27·6%) to streptomycin, 72 (7·9%) to aureomycin and terramycin, and 11 to chloramphenicol.

All the strains resistant to aureomycin were likewise resistant to terramycin, and vice versa. 98% of these strains were resistant to penicillin and 66% to penicillin and streptomycin. None of these strains was acquired outside the hospital. The first strains isolated were converted to resistance during aureomycin or terramycin therapy. Subsequently the strains were isolated from cases of hospital cross-infection.

A survey of the nasal carrier-rates in 200 of the hospital staff showed that 54·5% were carriers of *Staph. pyogenes*. Of every 10 carriers, 8 were carrying penicillin-resistant strains. 47% were carrying penicillin-streptomycin-resistant strains, and 17 carriers of penicillin-streptomycin-aureomycin-terramycin-resistant organisms of one particular phage type were found.

There was a close correspondence between the distribution of phage-types and antibiotic resistance in the strains from the patients and the noses of the staff.

This work was supported in part by a grant from the Australian National Health and Medical Research Council. It is a pleasure to acknowledge the technical assistance of Mr. G. Barr, Miss V. Sife, and Miss S. Garvin Smith.

THE MAINTENANCE THERAPY OF PERNICIOUS ANÆMIA WITH VITAMIN B_{12}

D. A. BREWERTON

PHYSICIAN

CENTRAL MIDDLESEX HOSPITAL, LONDON

VITAMIN B_{12} is being widely used in the treatment of pernicious anæmia. So far all the evidence shows that the initial response is good, but clinical and laboratory studies must be made over several years before vitamin B_{12} is fully accepted as the best maintenance therapy. It must be shown that adequate blood levels are maintained and that no neurological complications ensue. Also the patient's opinion of the new injections has to be considered, as well as the opinion of the neurologist and hæmatologist, for it is important to maintain well-being in addition to hæmatological and neurological perfection.

This study is based on 36 patients with pernicious anæmia who had previously been treated with liver preparations for at least a year (most of them for over five years) and now have been changed to a preparation of vitamin B_{12} for more than twenty months. They had their own opinions about the change of therapy, and these were recorded. Full clinical examinations and blood-counts were done at the time of review.

DOSAGE

At first small doses were given at short intervals, but with increasing knowledge we have come to rely on larger doses given every two to four weeks. At present the doses vary between 50 µg. every four weeks and 100 µg. every two weeks.

On liver therapy the patients required an average of one injection every nineteen days. On vitamin B_{12} they required an average of one injection every twenty-five days.

The cost of liver extract varies with different preparations. Our patients had been treated with one or more of five well-known proprietary preparations at an average cost per patient of £2 10*s.* a year, whereas treatment with a proprietary vitamin-B_{12} preparation ('Cytamen') cost on the average 9*s.* 4*d.* a year.

PATIENTS' OPINIONS

The following questions were asked of each patient: "Your injections were changed in ——. Have you been better or worse since then?" "Which injections do you prefer?"

3 patients felt worse since their injections were changed; 13 felt no difference; and 20 felt that they had improved.

Of the 3 patients who felt worse the 1st said: "I feel weak and I'm all of a shake." He has a senile tremor which has been becoming more severe for five years. Clinical examination revealed no evidence of subacute combined degeneration of the cord, or of peripheral neuritis, and a blood-count was normal, with 5,000,000 red cells per c.mm. The 2nd patient has had severe subacute combined degeneration of the cord since 1944. She complained that there was more cramp in her leg muscles at night. On examination there was no change in the physical signs, and a blood-count was normal. Her dosage was inadequate and has since been increased from 50 to 100 µg. every two weeks, with complete relief of her recent symptoms. The 3rd patient is a woman, aged 75, with chronic bronchitis. She complained that she was not so robust, and that her appetite was poor. On examination there were no abnormal signs, except those due to her bronchitis, and a blood-count was normal, with 4,600,000 red cells per c.mm. Review of her old notes revealed the same complaints recurring many times during the past ten years while she was having liver injections.

13 patients had noticed no improvement. Without exception these patients had had no symptoms when their therapy was changed. As one said, "I feel lovely, but I felt all right before."

The other patients, who all felt better, may be quoted verbatim:

(1) "I'm much better since I changed the injections. My breathing is better."

(2) "I think they're wonderful. I'm better this last eighteen months. Now I can do some housework, and before I couldn't hardly do anything. It is definitely better. I am so much better in myself."

(3) "They're better than the ones we had before. Not so tired."

(4) "I have been much better than on the other. I've always thought so. There's nothing wrong with me now. I've felt more life."

(5) "I've felt ever so much better, doctor. My cramp is much better."

(6) "I haven't been so tired. My legs haven't ached so much."

(7) "I am much better than I was with those dark injections. I feel better in myself. I can walk better." (This patient has angina of effort.)

(8) "These suit me well. I've felt much better since I've had that."

(9) "Better. Before I used to be tired. Now I just get on with my work."

(10) "I feel better."

(11) "I think I have felt definitely better. I can do more than what I did. I noticed it about six months after I changed."

(12) "I'm better. I have more go in me. I don't get so tired. I seem to be more energetic."

(13) "I know it was changed and I've been pleased ever since. It seems to suit me."

(14) "I feel a lot better in my health and everything. I don't want those first ones (liver) again. I feel champion."

(15) "I've been a lot better in all respects. I'm not so short-winded. I'm not so tired."

(16) "Ever so much better on this stuff. Now I feel quite normal. I don't feel tired or anything."

(17) "I have been better. I am not so short of breath. I have more go in me. I have more energy."

(18) "I am definitely better."

(19) "This treatment is superior to the other. I don't get so fatigued in the evenings."

(20) "I'm definitely better. The pains in the chest have gone (angina of effort). The pins-and-needles are better. I wouldn't like to change back, because there has been a definite improvement."

CLINICAL EXAMINATION

All the patients were examined clinically at the time of review. In no case was there clinical evidence of deterioration. Particular attention was paid to the nervous system. As already described, one patient complained of increased night cramp. No other new complaints and no new physical signs were elicited. No patients had developed neurological complications, and of 5 cases of subacute combined degeneration of the cord only the 1 case could be considered to be in any way worse than before the change of therapy. At the same time 3 of these patients said that their symptoms were less or that their walking had improved. In no case was there striking improvement.

BLOOD-COUNTS

Extensive laboratory investigations were not made. Hæmoglobin, red-cell count, packed cell volume, and blood film were done in all cases at least once at the time of review. These results will not be discussed except to say that all the counts were considered to be within normal limits. In no case was the red-cell count below 4,000,000 per c.mm. for women or 4,400,000 per c.mm. for men.

REACTIONS

Of the 36 patients who had had liver therapy for more than a year 13 (36%) had experienced unpleasant reactions after liver injections at some time. The commonest reaction was flushing of the face. As one patient said, "My face came up scarlet in the bus on the way home from hospital. I felt terrible, and there was no life in me. Sometimes I nearly fainted. But I was better the next day." One patient with chronic bronchitis experienced increased wheezing and dyspnœa for twenty-four hours after an injection. Fifteen patients complained that the liver injections they had had were painful. Sometimes the pain was such that they were unable to turn over in bed for two or three nights. In most instances these unpleasant reactions had been avoided by changing to another liver preparation.

In our experience of vitamin-B_{12} therapy there have been no reactions following about a thousand injections given to 40 patients. No patient found the injections painful, and in no case did a sterile abscess form.

DISCUSSION

During this investigation the most striking finding was the patients' enthusiasm for this treatment. Over half of those questioned stated clearly that they felt better and that symptoms had been relieved. Since their injections had often been changed before (from one brand of liver to another) they were not specially biased in favour of a new type of injection.

The subjective changes experienced by patients with pernicious anæmia are an important feature of this disease. Further, it is well known that many of the symptoms are not directly related to the anæmia or to neurological complications. This is shown most clearly when a case in relapse is treated with vitamin B_{12} or liver extract. Indigestion, vomiting, fever, lethargy, and mental symptoms may improve within a few hours. The appetite returns, and there is a feeling of well-being. All this happens before there is any change in the peripheral blood. Similarly, when a case begins to relapse, there are sometimes vague symptoms at an early stage before there is an appreciable alteration in the blood-count. The patient loses his sense of well-being.

Although our patients may feel better because of more adequate treatment of their pernicious anæmia, it is also possible that this improvement is due to a non-specific "tonic" effect. Such an effect has been attributed to vitamin B_{12} when given to patients with general debility. It seems impossible to determine which is the more important factor, but this does not detract from the value of the improvement.

CONCLUSION

Vitamin B_{12} is popular among patients who have pernicious anæmia and must have regular injections for the rest of their lives.

It is cheap, relatively painless, and free from unpleasant reactions. Its potency is reliable.

We wish to thank Dr. George Discombe, Dr. H. B. W. Greig, and the hæmatology technicians for their assistance in this work.

"When the physician takes the history of a patient with whom he has had no previous acquaintance, the interrogator's attitude toward that person and his reaction to his complaints will create more of an impression than his technical skill. The ability to be interested, unhurried, careful, tactful and considerate rather than amused, supercilious, distracted, bored or inconsiderate of the patient's sensibilities might well be called the essence of the art of medicine. . . . the student . . . should be reminded of the possible dire consequences of *showing the pity which he may feel for* an incurably ill patient, and the tragedy which may result if the patient, rather than a responsible member of his immediate family, is frankly told the truth."—SIMON S. LEOPOLD. *Principles and Methods of Physical Diagnosis.* Philadelphia and London, 1952; p. 403.

FURTHER OUTBREAK OF BORNHOLM DISEASE ASSOCIATED WITH COXSACKIE VIRUS

H. S. BURY
M.R.C.S., D.P.H.
MEDICAL OFFICER OF HEALTH, SADDLEWORTH URBAN DISTRICT COUNCIL

J. O'H. TOBIN
B.M. Oxfd, Dip. Bact.
LECTURER IN BACTERIOLOGY, UNIVERSITY OF MANCHESTER

SIX weeks after the localised outbreak of Bornholm disease in a suburb of Manchester, reported by Metcalfe Brown et al. (1952), another occured in a village in Saddleworth urban district 20 miles away. From 2 patients during this second epidemic Coxsackie virus was isolated which was of the same serological type as that found in the first epidemic.

This second outbreak took place between July 19 and 30, 1951. Of the 21 patients seen, 16 were children and 5 adults. Most of the children were attending two schools, situated at either end of the village, which appeared to be the foci from which the disease was disseminated: 13 patients were either at, or in contact with children attending, one school, and 7 were associated with the other. There was only 1 case, that of an old man, in which contact with the schools could not be established.

In the school initially affected the first 5 cases occurred in the infants' class within four days of each other: these were followed by 4 more cases four to eight days later, 2 in the same and 2 in another class. Of the children in this school, 1 infected a child of pre-school age who passed on the disease to his parents. Four days after the first case appeared, 2 older children attending the other school became ill, and 1 of them transmitted the disease to his mother and sister. Four days later 2 more children were taken ill at this school, but with the closing of the schools for the summer holidays the outbreak ceased abruptly.

As the majority of cases were contacts one with another, there was no reason to think that the infection was conveyed by vectors such as flies. The incubation period appeared to be two to four days.

CLINICAL FEATURES

Three different clinical types were noted, and these would have been attributed to different infections had it not been for their close association and the results of the virus studies.

TABLE I—CLINICAL SUMMARY

—	Types 1	2	3
No. of cases	11	5	6
Age-group			
3–5	9	1	0
7–10	2	4	0
Adults	0	0	6
Duration of illness			
1–3 days	11	5	2
1–2 weeks	0	0	4
Clinical symptoms			
Pyrexia	9	5	6
Sore throat	1	0	2
Muscle pain:			
generalised	0	0	2
abdominal	10	0	2
chest	2	0	1
limb	3	0	1
Neck pain or stiffness	1	1	4
Lassitude	2	3	0
Headache	3	4	6
Dizziness	2	2	2
Anorexia	0	1	3
Nausea or vomiting	5	3	1
Loose stools	0	2	0

Type 1.—These were typical cases of Bornholm disease with pyrexia and acute abdominal or chest pain, occurring mostly in the younger children.

Type 2.—In these cases the main symptoms were pyrexia and headache with occasional pain or stiffness in the neck, nausea or vomiting, and lassitude. The older children tended to present this sort of clinical picture in which there was no definite muscular involvement.

Type 3.—This type was characterised by headaches, neck stiffness, generalised or localised muscular pain, and sometimes dizziness. This syndrome was confined to the adults, in 4 of whom it lasted for a week or more.

A sporadic case (X.Y.) of this last type occurred in a village 3 miles away the day before the main outbreak. As serological studies were performed on the patient (table II) she was included in our summary of age-distribution, duration of illness, and symptoms (table I). Evidence of salmonella, shigella, or brucella infection was sought in 3 cases with negative results.

TABLE II—SERUM-NEUTRALISATION TESTS

Patient	Age	Clinical type	Days after onset of symptoms	Serum + 100 I.D.$_{50}$ virus. No. of infected mice/no. injected at a serum dilution of 1 in 10	1 in 50	1 in 250	1 in 1250

CASE-HISTORIES

The histories of 3 cases occurring in one family and 2 others are given below to illustrate the different clinical syndromes.

The Family Outbreak

A schoolboy (A.B.), aged 7, complained of a sore throat and malaise on the morning of July 23, and in the afternoon was seized with acute pain in the lower chest. This persisted until the evening, but next morning after vomiting once he was quite well.

Four days later, while out for a walk, his sister (B.B.), aged 4½, complained of pain in her legs and hips. This pain then moved to her abdomen and slowly abated and by next day, except for one bout of vomiting, she was perfectly well again.

Three days later her mother (C.B.) started to experience malaise, headache, sore throat, and pain in her upper abdomen. Next day she had a temperature 101°F with headache and pain in the back of her neck and back. Chloramphenicol was administered, but her pyrexia and pain lasted ten days. A sample of serum taken on the sixteenth day from the onset of symptoms gave a high titre to the isolated strain of Coxsackie virus (table II).

Type 2

A boy (D.E.), aged 9, complained of malaise and dizziness on July 28, with pyrexia (104·5°F) and some vomiting. Next day he passed three loose stools but by the third day was quite normal. A rising titre to the isolated strain of Coxsackie virus was demonstrated in his serum (table II).

Type 3

An old man (F.G.) of 75, under regular medical supervision for arteriosclerosis and subject to headaches and palpitations, suffered from a severe acute headache and dizziness and vomited several times. He was pyrexial and complained of stiffness of his neck and palpitations. His illness lasted seven days and he was still weak ten days later. A rising titre to the Coxsackie virus was demonstrated in his serum (table II).

VIRUS INVESTIGATION

Single specimens of stools were obtained from 7 patients between the second and twenty-first day after the onset of symptoms and from 2 of these the same serological strain of Coxsackie virus was isolated. One of these fæcal samples had been taken on the fourth and the other on the eleventh day of illness. Stools from all these 7 patients and from 6 others were again tested two months later but no virus was isolated.

Neutralisation tests using the isolated strain were performed in paired serum samples obtained from 7 patients and the results are shown in table II. These were performed in mice less than one day old. A significant rise in titre was obtained in 4 cases in which the first sample was taken within the first six days of illness, but in the other 3 taken later antibody was present to a high level in all specimens. Four serum samples were also tested for antibodies three to four months after infection, and these all showed as high a level of antibody as those taken after two to six weeks. One of three sera taken nine months later showed little if any drop in titre, but in the other two it had decreased —in one considerably. The sera of 4 adults living in the village who had slightly different pyrexial attacks were negative.

Histologically the strain of Coxsackie virus which was isolated produced lesions in fat, brain, and to only a very slight extent in muscle in mice one to two days old, and produced no visible signs in three-weeks-old or adult mice. However, histological examination of 6 three-weeks-old mice six and ten days after inoculation with a large dose showed an acute pancreatitis in one of them. These findings would place this agent in Dalldorf's group B. Involvement of the pancreas in older mice by a strain of this group was first reported by Pappenheimer et al. (1951) in the U.S.A. and has also been found in strains in Australia (Atkinson et al. 1951), and in Oxford (Sanders 1952).

By cross-neutralisation tests the virus from our Saddleworth cases was found to be of the same serological type as that isolated from the neighbouring epidemic in Baguley (Metcalfe Brown et al. 1952), but it was not related to the B1 strain, Conn 5 (see table III). The virus was not neutralised by antisera prepared against the group A strains 1, 2, 4, "Grey," and "Northwich," the last two strains being isolated in this country, "Grey" by Prof. C. H. Stuart Harris and "Northwich" (which is not identical with but is related to A1) by Forrester and Tobin (1951).

DISCUSSION

It is almost certain that members of the Coxsackie group of viruses are the causal agents of epidemic Bornholm disease. The close association of this illness with this type of virus infection has been shown in the United States, on the Continent, in Australia, and in this country. Recently Lepine et al. (1952) have isolated strains from muscle biopsy material taken during an epidemic and have noted the same histological response in the human subject as was seen in suckling mice. That cases of the three clinical types described here were suffering from the same virus infection was indicated by the virus studies. The virus was isolated from cases of type 1 and type 2. Previous work had shown that this strain had been associated with the type-1 clinical

of antibody was demonstrated in another case of type 2 and in 3 cases of type 3. The other 3 cases investigated serologically had large amounts of antibody in each sample of serum, but in all of these the first specimen had been collected after the first week of illness. To demonstrate a significant rise in titre the first serum sample should be taken within six days of the onset of the illness and preferably in the first one or two days. Neutralising antibodies appeared within the first week and rose steeply to a high level which was maintained for three to nine months but then slowly declined.

Two serum samples taken four months after the patients had had Bornholm disease were received from Dr. R. J. F. H. Pinsent of Birmingham, and three from Dr. J. Sandilands of Kirkcaldy; and all of them contained high levels of antibodies to this strain. Epidemics of the disease had occurred in both areas during the summer, one of which was reported by McNeish and Stewart (1952).

During the summer and autumn of 1951, 6 sporadic cases of myalgia from the North-West, 4 of which occurred in pairs, were tested against this strain with negative results. However, another serological type of Coxsackie virus was isolated from the son of one of the patients. This boy had a lymphocytic meningitis. The sera from 5 of these cases all contained antibody to high titre to this second type. The exact relation of this strain to the sporadic cases of Bornholm and to cases of aseptic meningitis has not yet been determined.

TABLE III—CROSS-NEUTRALISATION TESTS

Virus strain	Antiserum (Lowest dilution showing complete inhibition with approx. 100 I.D.₅₀ virus)				
..	Saddleworth	Baguley	Conn 5	A1, 2, 4	Grey and Northwich
Saddleworth ..	1/250	1/1250	<1/10	<1/10	<1/10
Baguley ..	1/250	1/1250	<1/10	<1/10	<1/10
Conn 5 ..	<1/10	<1/10	1/250	<1/10	<1/10

The rôle of Coxsackie virus in lymphocytic meningitis is still far from clear. The cases of headache and neck stiffness reported during the epidemic described here might suggest a meningeal reaction, but there was no clinical evidence to justify lumbar puncture. 9 cases of lymphocytic meningitis of unknown ætiology occurring in the North-West of England during the summer and autumn were investigated for neutralising antibodies against the Saddleworth strain of Coxsackie virus but all were negative. Of these 9 patients 3 lived in the affected village, but they were taken ill some weeks after the epidemic had finished. Of these cases, 2 failed to neutralise the second strain.

At the moment it would appear that in the North-West of England the explosive outbreaks and a few of the sporadic cases of Bornholm disease were due to the same type of virus, while the more sporadic cases were probably caused by another type occurring simultaneously in the locality. Whether the difference in epidemiology of these strains is related to a biological as well as serological difference has not yet been decided, but comparison between other strains isolated elsewhere in the country may provide the answer.

SUMMARY

An outbreak of Bornholm disease associated with a Coxsackie virus is described. Three different clinical types of infection were noted and case-notes are given to illustrate each. The relation of *Coxsackie* virus to myalgia and lymphocytic *meningitis* in the North-West

Our thanks are due to Dr. D. McCracken and Dr. R. S. Holgate for reporting cases; to Dr. M. T. Parker, Dr. W. H. Patterson, and Dr. K. Rawnsley for samples of serum from sporadic cases of myalgia; and to Dr. A. D. Macrae for strains of Coxsackie virus.

INTRA-ARTICULAR HYDROCORTISONE ACETATE IN RHEUMATOID ARTHRITIS

G. D. KERSLEY
T.D., M.A., M.D. Camb., F.R.C.P.
PHYSICIAN, ROYAL NATIONAL HOSPITAL FOR RHEUMATIC DISEASES, BATH

M. H. L. DESMARAIS

NUFFIELD RESEARCH FELLOW

From the Rheumatism Research Unit, Royal National Hospital for Rheumatic Diseases, Bath

A FEW reports have appeared in America on the use of hydrocortisone acetate (Compound F) in rheumatoid arthritis (Thorn, G., cited by Hollander et al. 1951, Stevenson et al. 1952) but so far there has been none in this country. We are therefore presenting this preliminary report comparing its effects with those of cortisone (Compound E) when injected into affected joints.

In 11 patients with rheumatoid arthritis 32 intra-articular injections of hydrocortisone acetate were given into 14 different joints.

In 3 patients whose two knees had been affected for about the same time and were about equally swollen, cortisone was injected into one knee and hydrocortisone into the other. In a second series of 8 cases, 13 joints were injected first with cortisone and later with hydrocortisone.

Each injection consisted of 50 mg. of cortisone or 50 mg. of the saline suspension of hydrocortisone acetate; the patients did not know which drug was being administered. Progress was assessed every other day, the range of movement, circumference of the joint, and amount of tenderness being recorded on a graph. The injections were not repeated until the symptoms returned.

In the 3 patients given cortisone into one knee and hydrocortisone into the other, the knees injected with cortisone showed only slight improvement lasting for about three days. But of the 3 knees injected with hydrocortisone, 2 showed dramatic improvement, lasting for eight days in one and fifteen days in the other, after a single injection; the third knee was slightly improved for three days after each of two injections—an effect comparable with that of cortisone in the opposite knee.

In the 8 cases treated first with cortisone and then with hydrocortisone, 5 of the 13 knees injected with cortisone showed slight improvement for twenty-four to forty-eight hours, the others being unaffected. However, 4 of these 8 cases reacted sharply to hydrocortisone, the average duration of improvement after each of 17 injections into 8 joints being fourteen days. In 1 case there was complete freedom from symptoms in both knees a month after the last injection; 1 case showed moderate improvement for three days only; 1 case showed slight improvement after the first two injections, moderate improvement with the third, and no benefit at all from the fourth, fifth, and sixth injections. One case, which had proved completely resistant to systemic cortisone and intravenous adrenocorticotrophic hormone, did not respond to the injection of hydrocortisone into a wrist, but a single injection of hydrocortisone into a recently swollen knee somewhat reduced both pain and swelling (Kersley et al. 1952).

In 5 cases where eosinophil-counts were done, there was a 50% fall in 2 cases after cortisone but in only 1 case after hydrocortisone. As these patients were having both knees injected at the same time, their total dose of cortisone and hydrocortisone was 100 mg.

In 6 cases synovial fluid was withdrawn for examination just before and two days after hydrocortisone injection, the aim being to draw off 2–3 ml. the minimal amount needed for these investigations, but in only 3 was enough fluid obtained on both occasions to compare the viscosities. In all 6 cases the total cell-count and percentage of polymorphs were reduced, with a relative increase in lymphocytes; and in the 3 cases where it was estimated the viscosity was increased (see table). In 6 instances intra-articular cortisone caused either no significant change or an increase in the synovial-fluid cell-count and had no significant effect on the ratio of lymphocytes to polymorphs; in 1 case out of 4 the viscosity was appreciably increased (see table).

In no case did any joint other than the one injected appear to benefit from the cortisone or hydrocortisone, and there was no apparent systemic effect. After the injection of hydrocortisone, improvement was usually noticed within about six hours and reached its peak in forty-eight to seventy-two hours. Of the 32 injections given, 22 produced striking improvement and only 4 were completely ineffective.

SYNOVIAL FLUID BEFORE AND 2 DAYS AFTER INTRA-ARTICULAR INJECTION OF 50 MG. OF CORTISONE OR HYDROCORTISONE

Drug injected	Total cells per c.mm.		Lymphocytes %		Polymorphs %		Viscosity	
	Before	After	Before	After	Before	After	Before	After
Hydrocortisone	7400	4500	22	47	76	21	750	1200
Hydrocortisone	60,800	29,500	7	10	92	83	340	1000
Hydrocortisone	36,000	30,000	6	25	92	69	820	2400
Hydrocortisone	19,000	8000	14	45	82	43	..	..
Hydrocortisone	68,800	11,150	8	39	86	59	..	..
Hydrocortisone	36,200	3400	8	51	88	31	..	..
Cortisone ..	37,200	31,000	7	7	91	88	..	
Cortisone ..	30,600	68,800	9	8	85	86	960	1157
Cortisone ..	27,200	35,600	8	10	85	88	680	487
Cortisone ..	32,000	66,000	8	4	88	94	910	1100
Cortisone ..	9900	13,800	26	16	71	76	..	
Cortisone ..	18,200	17,700	8	18	90	80	1200	6500

From this preliminary experience, hydrocortisone seems likely to have several valuable applications in the treatment of a refractory joint in a patient whose disease is otherwise well controlled, in monarticular cases, and as an adjunct to manipulation or orthopædic surgery, with the object of minimising joint reaction and subsequent formation of adhesions.

Hydrocortisone costs considerably more than cortisone at present, but when supplies improve the small quantity required should make it an economic proposition for selected cases.

We are indebted to Messrs. Merck and Co., for the hydrocortisone acetate used in this trial.

PANCREATICOGASTROSTOMY

R. INGEBRIGTSEN
M.D.
PROFESSOR OF SURGERY

E. LANGFELDT
M.D.
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY

UNIVERSITY OF OSLO, NORWAY

THE best method of establishing in man a communication between the canal of Wirsung and the alimentary canal after partial pancreaticoduodenectomy is still under discussion.

Wells and Annis (1949) showed th[illegible] trostomy was feasible in dogs, and [illegible] and Dill-Russell (1952) report the successful performance of this operation in man.

When one of us (R. I.) did his first pancreaticoduodenectomy three years ago, the pancreatic remnant was anastomosed not to the jejunum but to the stomach, on the supposition that the stomach, being more substantial than the jejunum, would hold the suture better than the jejunum would. Moreover, it was thought desirable to get rid of the hydrochloric acid of the stomach, which might perhaps destroy the trypsin secreted by the pancreatic remnant; and in any case it would be impossible to confirm postoperatively the presence of trypsin in the acid milieu of the stomach. In both the cases reported here I resected the antrum of the stomach, so that it contained no free acid postoperatively. This made it possible to test for pancreatic enzymes in the stomach after pancreaticogastrostomy. The investigations were made at the Physiological Institute of the University of Oslo under the direction of the other author (E. L.).

After excision of the head of the pancreas with the duodenum, resection of the gastric antrum, choledochojejunostomy, jejunogastrostomy, and pancreaticogastrostomy, a test-meal withdrawn from the stomach may contain trypsin, lipase, and diastase secreted by the pancreatic stump implanted in the gastric wall, diastase from the saliva, pepsin and lipase from the stomach, and erepsin and bile from the intestine. Hydrochloric acid is not to be expected, because the antrum is excised, but bile is always present. If trypsin is found, it means that the pancreatic stump, implanted in the gastric wall, is secreting; for trypsin is the proteolytic enzyme of the pancreatic juice and is the only enzyme which splits true proteins (e.g., serum-proteins) into amino-acids. The splitting takes place only in an alkaline milieu, the optimum pH being about 8·5.

Erepsin is the proteolytic enzyme of the intestinal juice. It does not act, however, on true proteins, though it catalyses the splitting of peptones in an alkaline milieu. Pepsin splits proteins into peptones but not further, and is active only in an acid milieu. Since the contents of the stomach after [illegible] are not acid, pepsin does not [illegible]ion in an alkaline milieu. One may conclude that trypsin is present if serum-protein is used as the substrate in an alkaline milieu and hydrolysis is demonstrated. If peptones are used as the substrate in an alkaline milieu, hydrolysis is effected by erepsin as well as by trypsin.

METHODS

Two simple methods can be used:

(1) 1 ml. of stomach contents is mixed in a glass with 10 ml. of 4% peptone solution, and 1 ml. of stomach contents in another glass with 10 ml. of serum-protein solution. To each glass is added *N*/10 sodium hydroxide to bring the pH to 8·3. The two solutions are kept at a temperature of 37°C and examined at intervals for turbidity when 1 ml. is mixed with 10% trichloracetic acid. Amino-acids give no turbidity. Trypsin gives turbidity in both solutions. Erepsin gives turbidity with peptone but not with serum-protein.

(2) Formol titration is a quantitative method which may be used for qualitative analysis: 50 ml. of 4% peptone solution and 50 ml. of 4% serum-protein solution are each mixed with 5 ml. of stomach contents. The blank value is determined in 10 ml. of the mixture, which is next kept at a temperature of 37°C. Formol titration of 10 ml. is done after 2 hours, 5 hours, and 24 hours. The titration acidity, expressed in ml. of *N*/10 sodium hydroxide, will be the same as the blank value if trypsin is absent. If trypsin is present, formol titration with serum-proteins will show that the solution contains an enzyme hydrolysing proteins in an alkaline milieu and that the hydrolysis goes further than to peptones.

The pancreatic juice also contains a very active lipase which acts in an alkaline milieu, splitting neutral fat to glycerol and fatty acids. If an emulsion of neutral fat, with a pH of 8·5 and containing an enzyme, changes from alkaline to acid, and if lipolysis can be proved again and again after the acid mixture has once more been made alkaline, we may conclude that lipase is present. A lipase with these qualities is found only in the pancreatic juice.

CASE-RECORDS

Case 1.—A man, aged 55, was admitted to the University Hospital on Feb. 12, 1949, with five weeks' history of abdominal pain, chills, fever, and jaundice. Radiography showed no calculi in the gall-bladder, or elsewhere. A gall-stone in the common bile-duct was diagnosed.

Operations.—Laparotomy on Feb. 13 revealed a carcinoma of the head of the pancreas. No calculi were found. A cholecystogastrostomy was done successfully, and the jaundice and fever subsided. At laparotomy two months later no metastases were found, and a pancreaticoduodenectomy was performed (carcinoma of the pancreas was confirmed histologically), the gall-bladder and the antrum of the stomach were removed, the common bile-duct was anastomosed to the jejunum, the remnant (about half) of the pancreas histologically free from cancer was sutured in three layers into an opening in the posterior wall of the stomach, the duct of Wirsung was dilated rather easily, and the stomach was anastomosed to the jejunum, end to side.

Postoperative course was uneventful and without glycosuria. An Ewald test-meal showed no free acid and a total acidity of 13.

Formol titration of the gastric contents for pancreatic enzymes after a test-meal of 200 ml. of barley-soup withdrawn after 1 hour (the stomach had been evacuated by aspiration just before the test-meal was given) gave the following results:

	Peptone	*Serum-protein*
0 hr.	5·0 ml. *N*/10 NaOH	1·9 ml. *N*/10 NaOH
2 ,,	5·6 ,, ,,	2·2 ,, ,,
5 ,,	6·6 ,, ,,	3·2 ,, ,,
24 ,,	12·0 ,, ,,	3·3 ,, ,,

This showed that trypsin was present.

The presence of lipase was proved by shaking a sample of the stomach contents with olive oil in water, with phenolphthalein added as an indicator, and *N*/10 sodium hydroxide to pH 8·3, and leaving the mixture until the red colour had disappeared, adding *N*/10 sodium hydroxide until it became pale rose, then leaving it again till this colour disappeared, and adding *N*/10 sodium hydroxide again, and so on.

Follow-up.—Three months after the pancreaticoduodenectomy the patient resumed his former occupation. Four months later he had two hard tumours in his abdomen, each as big as a child's fist—evidently recurrent cancer—and he died shortly afterwards. There was no necropsy.

Case 2.—A man, aged 51, was admitted to the University Hospital on Nov. 17, 1949, with four weeks' history of diarrhœa, loss of weight, itching, dark urine, and progressive jaundice. There was no pyrexia. Obstructive jaundice, probably caused by a tumour, was diagnosed.

Operations.—On Dec. 21 laparotomy revealed an induration of the lower right corner of the pancreas. The gall-bladder, which was much dilated but had no calculi, was anastomosed to a loop of the jejunum, the two limbs of the latter being connected to each other by an entero-anastomosis. It proved impossible to pass a sound to the duodenum through a choledochotomy. After the patient had recovered from this operation and the jaundice had subsided, a pancreaticoduodenectomy was performed on Dec. 30. The dissection of the duodenum from the posterior abdominal wall was rather laborious, the tissue here being sclerotic. Tumour tissue had grown far and deep through the wall of the duodenum into the retroperitoneal tissue and had spread along the sheath of the vena cava. Cancer here was verified histologically, the tumour being an adenocarcinoma originating from the ampulla of Vater. Radical excision was impossible for remnants of tumour tissue were sure to be left behind. This only became evident, however, when the operation had gone too far. The common duct was anastomosed to the loop of jejunum already connected to the gall-bladder. The pyloric antrum of the stomach was resected, and an end-to-side gastrojejunostomy was done. The cut end of the pancreas was implanted into the posterior wall of the stomach by sutures in three layers.

The postoperative course was uneventful and without glycosuria. On admission to the surgical department on Dec. 6, 1949, the patient had weighed 62·8 kg., and on discharge on Feb. 27, 1950, 58·7 kg. On two occasions the stomach contents were examined for pancreatic enzymes, and trypsin was found, though in considerably smaller amounts than in case 1.

Follow-up.—On March 31, 1950, the patient weighed 62 kg. He then went away and we did not see him again, but his doctor reported that he died with cachexia six months after the pancreaticoduodenectomy.

SUMMARY

In two patients the stump of the pancreas was implanted into the stomach after pancreaticoduodenectomy, an extensive resection of the gastric antrum being done at the same time to get rid of the gastric hydrochloric acid.

Both patients made a good postoperative recovery. Both gained weight, and one of them resumed work. In both cases pancreatic enzymes were found in the gastric contents after the operations.

The operations therefore seemed to be technically and physiologically successful.

RECOVERY FROM A SHOT IN THE BACK OF THE NECK

K. Várady
M.D. Budapest

In the case reported here a pistol shot was fired at close quarters at the back of a woman's neck without killing her; in fact later she was restored to perfect health.

CASE-RECORD

A woman, aged about 30, well developed, strong, and otherwise healthy, was blindfolded and led to the edge of a deep ditch. There she was shot in the back of the neck with a pistol and fell into the ditch, breaking a few ribs and acquiring a hæmothorax. After some time she regained consciousness, tried to climb out, and was seen by passers-by, who carried her away for proper medical treatment.

On examination the back of her neck showed a fresh bullet-wound in the midst of hair sticky with blood; no exit wound could be detected. Radiography revealed a pistol bullet in the midline behind the posterior tubercle of the atlas (fig. 1).

Treatment.—The bullet was removed *secundum artem*, and the patient recovered completely in spite of the most unfavourable circumstances then prevailing (1944).

DISCUSSION

A shot fired at close quarters at the back of the neck from the direction indicated by the arrow in fig. 3 practically always causes death. After breaking through the occipital bone, or piercing the foramen magnum, and entering the skull the projectile will either damage the brain directly or hydrodynamically, or, without penetrating the skull, injure the vital organs passing through the foramen magnum—the medulla oblongata, the vertebral artery, the spinal arteries, the accessory nerve, and the 1st cervical nerve. Therefore this type of shot is well known for its lethal effect and is used in practice. It may be applied, though with some difficulty, to one's own neck for suicidal purposes, as reported by Maschka and by Haberda at the end of the last century.

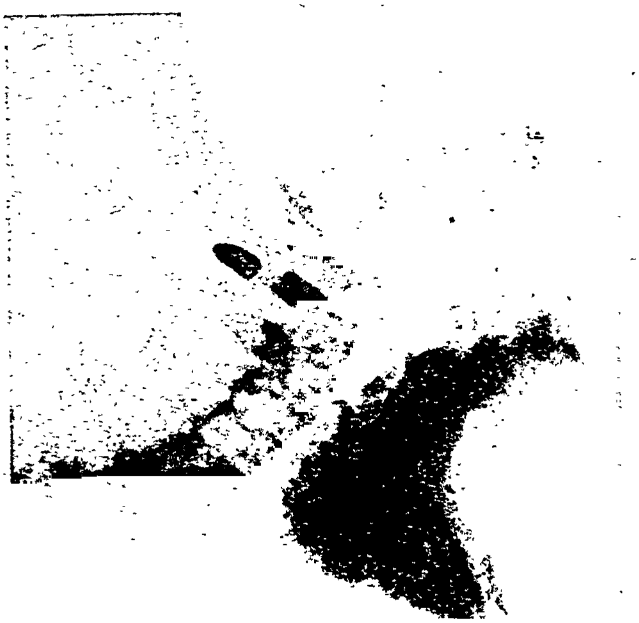

Fig. 1—The pistol bullet behind the posterior tubercle of the atlas and pointing outwards.

Radiography in the present case showed that the bullet had turned completely round to point to the surface again and had become bent in the process (fig. 1). The bullet had finally come to rest behind the posterior tubercle of the atlas. These three facts show that the bullet must have ricochetted from the skull, missing the vital parts of the neck. The radiogram did not show any fracture.

The wound presented a strange feature: the small perforation of the entrance wound communicated, immediately under the skin, with an egg-sized cavity with uneven walls lined with shreds of soft tissue and containing clotted blood and the bullet.

The fact that the bullet neither entered the skull nor penetrated deeper into the neck may be explained by the circumstance that the bullet, passing through and being retarded by the ligamentum nuchæ (fig. 2), struck the external occipital crest at an acute angle. Here the force of impact slightly bent the bullet and deflected its course. The diverted bullet could hardly pierce the relaxed septum nuchæ, because its kinetic energy had been spent on complicated rotations destroying the surrounding tissues instead of driving itself forward in the prolongation of the trajectory (fig. 3).

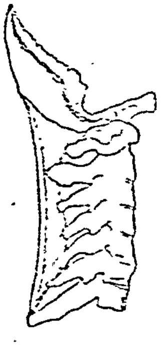

Fig. 2—The ligamentum and septum nuchæ.

This explanation is supported by the following facts:

(1) The patient was young, with well-developed bones and elastic tissue.

(2) The occipital bone is thickest in the midline, where the bullet struck; here it is formed by the external and internal occipital protuberances and the external and internal occipital crests.

(3) The ligamentum and septum nuchæ (fig. 2) are thick, very tough, and extremely elastic, apt to reduce or damp the motion of a projectile.

(4) A projectile ricochetting within the body may perform all kinds of rotatory movements and dig a cavity. Thus, by
